Graphene could play a significant role in MRAM, specifically, it has been shown to act as a highly efficient diffusion barrier, able to unlock atomic layer deposition processes or to provide encapsulation or large TMR values, which can be tunable (Piquemal-Banci et al., 2017; Avsar et al., 2020; Dayen et al., 2020; Vedmedenko et al., 2020; Yang et al., 2022; Och et al., 2021). The latter are comparable to those reported in early generation AlO_x-based MTJs, but still not competitive with CoFeB/MgO based MTJs. FM junctions have successfully been fabricated with other 2D barriers such as hBN and TMDCs (Dayen et al., 2020; Och et al., 2021). In all these cases, the coupling between the 2D material and the FM plays a crucial role in determining the spin polarization and (magnetic) proximity effects. Other remarkable phenomena involving graphene, important for MRAM, include the PMA enhancement in Co-graphene and the possibility of creating artificial AFMs out of graphene-Co/graphene/Co multilayers.

Relevant TMDCs for spintronics exhibit semiconducting, metallic or semi-metallic behaviors. Among those materials belonging to the first group, WS₂ and MoS₂ have demonstrated significant spin-filtering with TMR approaching 100% and predictions orders of magnitude larger (Dayen et al., 2020). TMDCs are also potentially useful SOT materials. The reduced crystal symmetries of some TMDCs, such as semi-metallic WTe₂, can lead to unconventional torque components that are required for field-free switching in perpendicularly magnetized MRAMs (Yang et al., 2022). The SOT has been investigated using MoS₂, WSe₂, and WTe₂ as SOT materials both in hybrid 2D/3D and all-2D systems (Liu and Shao, 2020; Hidding and Guimarães, 2020; Kurebayashi et al., 2022). Magnetization switching has been observed although in a regime of domain wall motion (Yang et al., 2022).

Beyond TMDCs, efficient SOTs have been reported with vdW TIs of the (Bi_{1-x}Sb_x)₂(Te_{1-y}Se_y)₃ family of materials, as already discussed in Section “Conventional materials and current applications” (Yang et al., 2022). The fact that processing tools for physical vapor deposition, which are standard to deposit MTJ stacks, can be used for TI layers with high SOT efficiency, despite the polycrystalline nature and chemical disorder, is encouraging toward the realization of TI-based MRAM. Open questions remain concerning the presence of strong intermixing between conventional FMs and the TI, damage due to the 400 °C heat treatment required by CMOS processing, and topological against bulk origin of the spin current responsible for the observed SOTs (Galceran et al., 2021).

Further opportunities are present in opto-spintronics devices. In the monolayer limit, semiconducting TMDCs become direct band-gap semiconductors with the valley states at the *K* and *K'* points in reciprocal space being strongly coupled to the spin degree of freedom (Manzeli et al., 2017; Avsar et al., 2020; Vedmedenko et al., 2020). Circularly polarized light can excite a selected valley. Using time resolved Kerr rotation, spin-valley lifetimes in the microsecond scale have been observed at cryogenic temperatures. The suppression of the exciton-valley depolarization channel in WS₂-WSe₂ heterostructures has led to hole spin-valley lifetimes in WSe₂ in excess of 20 μ s and propagation lengths of over 20 μ m. Notably, optical generation of spin-valley polarized carriers in the TMDC can be used to inject spins into a neighboring graphene layer, providing an alternative to spin injection from FM electrodes. This has been demonstrated in MoS₂- and WSe₂-graphene heterostructures (Avsar et al., 2020; Vedmedenko et al., 2020; Sierra et al., 2021).

Magnetic proximity effects are also intensively studied in TMDCs and in TIs (Sierra et al., 2021). In TMDCs, the exchange splitting has been quantified with the reflection and photoluminescence spectra of circularly polarized light. The exchange field in WSe₂- and WS₂-EuS has been estimated in the scale of 10 and 100 T, respectively. In all-2D structures, such as WSe₂-CrI₃, the proximity effect has been found to be layered-dependent, with the largest contribution to the magnetic exchange originating from the CrI₃ interfacial layer. Some compelling signatures of magnetism in TIs have also been reported, in proximity with YIG, EuS, and other magnetic insulators, including some vdW materials. However, most of these results rely on transport experiments that are currently not fully understood.

The most recent and arguably fastest growing class of 2D materials relevant for spintronics are vdW magnets, including FMs, AFMs and, possibly, altermagnets (see Section “Antiferromagnets and altermagnets”) (Gibertini et al., 2019; Och et al., 2021; Wang

et al., 2022; Kurebayashi et al., 2022). Reports on monolayer materials of CrSiTe_3 and of the MPX_3 family ($M = \text{Fe, Mn, Ni, Cd}$; $X = \text{S, Se}$) started to appear in 2016. The following year, conclusive evidence of magnetism was observed in CrI_3 and $\text{Cr}_2\text{Ge}_2\text{Te}_6$. Their respective Curie temperatures T_C were well below 50 K in the thinnest layers investigated (monolayer CrI_3 and bilayer $\text{Cr}_2\text{Ge}_2\text{Te}_6$). Nevertheless, these results triggered intense research on 2D magnets, and a frantic search for 2D magnetism at room temperature. Possible room-temperature magnetism was reported in VSe_2 and MnSe_2 . One advantage of thin 2D materials is their potential gate tunability and the likely maximization of VCMA (Gibertini et al., 2019). Using ion gating increased the T_C of $\text{Cr}_2\text{Ge}_2\text{Te}_6$ from 60 K to nearly 200 K. A promising material with PMA is metallic Fe_3GeTe_2 , with a $T_C \sim 230$ K. Changing the Fe content x from 3 to 5 increased the T_C to just above room temperature, although results indicate a transition to in-plane anisotropy. An even larger T_C has been reported in Fe_3GaTe_2 , when Fe is substituted with Co in Fe_xGeTe_2 and in $\text{Bi}_2\text{Te}_3/\text{Fe}_3\text{GeTe}_2$. The latter results, originally attributed to proximity effects, are not yet well understood. Another system of interest is Cr_xTe_y , which has significant complexity because of the large number of phases with different Cr and Te stoichiometry, some of them not truly vdW materials. Room temperature magnetism has also been reported in CrTe_2 , Cr_2Te_3 and in V-doped WSe_2 .

Large TMR (160%) has been observed in all-2D $\text{Fe}_3\text{GeTe}_2/\text{hBN}/\text{Fe}_3\text{GeTe}_2$, with even larger values predicted, including other barrier materials (Yang et al., 2022). A notable TMR exceeding 19,000% was observed in tunnel junctions with four layers of CrI_3 . The coercivity in $\text{WTe}_2/\text{Fe}_3\text{GeTe}_2$ can be modulated with current, while SOT switching has been achieved up to 200 K in this system. Another area of intense research involves magnetic skyrmions, which have been observed in several pristine 2D magnets and 2D-magnet based heterostructures.

Antiferromagnets and altermagnets

Antiferromagnets

The recently established field of antiferromagnetic spintronics takes AFMs as the central active elements of a device-focused system (Jungwirth et al., 2016, 2018; Baltz et al., 2018). It aims at demonstrating a range of functionalities, such as memory devices based on the electrical and optical control of the Néel magnetic order, and at exploring noncollinear AFMs, hybrid AFM/FM systems, artificial realizations of AFMs in multilayer structures, and the interplay of AFMs with topological phenomena. The approach promises important advantages. The compensated magnetic order in AFMs—both collinear, noncollinear, and non-coplanar with zero magnetization—makes them insensible to external magnetic fields and is favorable for memory device densification. The high resonant frequencies of AFMs—typically of the order of THz due to the exchange enhancement effect that couples the different spin sublattices—makes them natural candidates for optical manipulation devices bridging the THz communication gap.

A challenge to integrate AFMs into present technological memory devices is the fact that their electronic structure is spin-degenerate—in the absence of SOI—and often electrically inactive, i.e., insulating. From symmetry considerations, GMR/TMR and STT effects are excluded for readout or manipulation. Therefore, in many aspects, conventional AFMs are akin to non-magnetic materials, and invisible to the macroscopic electrical or optical probes commonly used in FMs. The lack of time-reversal symmetry breaking in reciprocal space further implies that the effects associated with the direct manipulation of AFMs magnetic order must arise from SOI (relativistic) origins, which are relatively weak compared to exchange-mediated effects. An example of this manipulation is the Néel SOT where a current-induced spin accumulation couples directly to the Néel order parameter and can rotate it (Železný et al., 2018; Manchon et al., 2019). This can occur in a co-linear AFM with two sublattices possessing opposite inversion symmetry breaking. Two of the key materials fulfilling this requirement are Mn_2Au and CuMnAs .

From the symmetry perspective, any response that is proportional to the orientation of the order parameter will be observable in the electronic transport and optical regimes. For transport, this is the case for AMR, which has been observed in many AFMs. The AMR indicates up to a 90 degree rotation of the Néel vector, which can be measured either by electron tunnelling or dc-transport (Železný et al., 2018). The tunnelling AMR in AFMs was first demonstrated experimentally in a $\text{NiFe}/\text{IrMn}/\text{MgO}/\text{Pt}$ tunnelling junction, while AMR was exploited in FeRu in one of the first AFM memory prototypes. A more direct visualization of the Néel vector can be achieved by X-ray magnetic linear dichroism (XMLD). Indeed, XMLD—photoemission electron microscopy (XMLD-PEEM) in CuMnAs confirmed the control of the Néel vector with Néel SOT (observed with AMR) when changing the polarity and direction of the applied current (Němec et al., 2018). While current-induced manipulation of the AFM order requires metallic materials, functional AFMs can be insulating. In this context, current induced switching has been demonstrated in NiO/Pt bilayer systems by exploiting the spin-Hall magnetoresistance effect in combination with XMLD-PEEM imaging.

AFMs, as many other materials, offer the possibility to generate SHEs and related spin-dependent transport, which are associated primarily with paramagnets. This is due to their spin-degenerate band structure, which is only lifted by SOI. There are many materials investigated in this context, including MnX , $X = \text{Fe, Pd, Ir and Pt}$. The magnitude of the SOTs generated by the spin Hall currents in these materials can compete with those in heavy metals (Manson et al., 2019). Switching of FMs with AFMs has been demonstrated while the exchange coupling felt by the FM enables field-free switching.

Other active areas are the study of the topology in AFMs and AFM opto-spintronics (Němec et al., 2018; Šmejkal et al., 2018). Soon after the discovery of graphene, layered AFMs of the SrMnBi_2 -type were reported to show massive Dirac quasiparticles near the Fermi level and quasi-two-dimensional quantum transport. The AFM order of Eu moments in EuMnBi_2 was found to change the interlayer conduction of quasi-2D Dirac carriers, tuning the transport in the quantum Hall regime. At the same time, CuMnAs was predicted to be a topological Dirac semimetal in its orthorhombic phase with the quasiparticle protection arising from non-symmorphic symmetries. A Weyl semimetal state could also emerge, which was first proposed in pyrochlore AFMs. Nontrivial surface states (the Fermi arcs connecting surface projections of the Weyl points) were predicted for the chiral non-collinear AFM

Mn₃Ge. Weyl semimetal states could also be realized in the paramagnetic and AFM phase of GdPtBi. The presence of Weyl points in the pyrochlore Eu₂Ir₂O₇ was inferred from optical experiments. However, despite an extensive effort, a clear material candidate for AFM Weyl semimetal remains elusive.

Light has been shown to be an efficient tool to control and detect spins and their ultrafast dynamics in AFM materials (Němec et al., 2018). As mentioned already, XMLD has proven vital in visualizing AFM domain structures. As with AMR, the quadratic dependence of the permittivity on the AFM order parameter is revealed in the magneto-refraction and magneto-absorption. The effects were observed as an intensity change of the diffracted X-rays in La_{0.5}Sr_{1.5}MnO₄, transmitted or reflected light in EuTe, FeRh and Cr₂O₃. A key aspect of AFM opto-spintronics is the ultrafast modification of the magnetic order. Femto-second lasers have made this field thrive. The first prediction focused on NiO, however, a key observation was the AFM to paramagnetic optically induced transition in the canted antiferromagnet iron borate FeBO₃, arising from an increase in magnon temperature transferred from the lattice. The ultrafast laser-induced reorientation of spins (Kirilyuk et al., 2010) in an AFM was shown in the dielectric orthoferrite TmFeO₃ where a temperature-dependent magnetic anisotropy is observed at 80–91 K. Related effects are reviewed extensively in Němec et al. (2018).

Altermagnets

As discussed above, the compensated magnetic order of AFMs makes them insensitive to moderate magnetic fields. At the same time, because their electronic band structure is spin degenerate—as mandated by non-relativistic symmetries—manipulation by electrical means must arise from relativistic SOI effects. This entails that, in order to control them electrically, we must circumvent the fact that their spin-responses are relatively weak, as compared to the strong spin-responses of FMs.

A direct solution to this problem comes in the discovery of a novel class of magnetic order with zero net magnetization termed altermagnetism (Šmejkal et al., 2022a,b). Altermagnets exhibit broken time-symmetry responses to an electric field akin to FMs, e.g., spin-polarized currents, and have unique properties, such as strongly asymmetric spin-polarized current response, where, for instance, a change of the current direction by 90 degrees can reverse the polarization of the current. The three collinear magnetic order classes—ferromagnetism, antiferromagnetism, and altermagnetism—are illustrated in Fig. 3. Conventional FMs are ordered in space and have principally isotropic (*s*-wave) spin-polarization order parameter in the electronic structure, Fig. 3 (left panel). AFMs are spin ordered in direct space but have no spin order, i.e., they are spin degenerate, in reciprocal space, Fig. 3 (middle). In contrast, altermagnets have an anisotropic (*d*-, *g*-, or *i*-wave) spin-polarization order, Fig. 3 (right), the naming arising from the alternating spin splitting in reciprocal space (Šmejkal et al., 2022b).

Shortly after the theoretical predictions of altermagnets, supporting evidence was shown by experiments detecting the AHE and spin-polarized currents in *d*-wave RuO₂ and Mn₅Si₃ and the anomalous Hall current in a *g*-wave MnTe. Besides these initial results, the predictions of GMR, TMR, or STT in altermagnetic multi-layer devices has opened a new avenue for spintronics, without the limiting downscaling of non-zero magnetization materials and allowing for charge-spin conversion without relying directly on SOI. This is the case for RuO₂, where its *d*-wave anisotropy of the spin-split Fermi surface allows for a pure spin currents transverse to the charge current, but without any connection to the SOI and, therefore, a potentially large λ_s . The propagation angle between spin-up and spin-down currents has been calculated to reach 34%, larger than in any known non-magnetic charge-spin conversion materials. A further unique effect is that the spin-polarized current in *d*-wave magnetic materials is the switching of the current's spin polarization when the current direction rotates by 90 degrees. There is no counterpart of this effect in the *s*-wave FMs, where polarization reversal only arises from a switching of the magnetization direction.

The basic steps to determine the altermagnetic spin group of a material are to identify: (i) the crystallographic group, (ii) the crystallographic group of the spin-sublattice (in the case of bipartite lattice the spin sublattice point group corresponds directly to Wyckoff position point group), and (iii) the crystallographic rotation transformation connecting the opposite-spin sublattices. For a full discussion of the symmetry considerations and classifications of altermagnets, we refer the reader to Šmejkal et al. (2022b). Material candidates for altermagnetism include both 3D and 2D crystals, in different structural or chemistry types, and can span the entire conduction spectrum from insulators, semiconductors and semimetals, to metals and superconductors. They include quasi-2D oxide insulator V₂Se₂O, semimetal Cr₂O, 3D rutile fluoride or oxide insulators FeF₂, MnF₂, MnO₂ and metal RuO₂, perovskite oxide

Fig. 3 Illustrative models of collinear ferromagnetism (left), antiferromagnetism (middle) and altermagnetism (right) showing the crystal-structure in direct space and non-relativistic electronic-structure in reciprocal space. Figure adapted from Šmejkal L, Sinova J, Jungwirth T (2022) Emerging Research Landscape of Altermagnetism. *Physical Review X*, 12, 040501. <https://doi.org/10.1103/PhysRevX.12.040501>.

insulators LaMnO_3 , CaCrO_3 and parent cuprate of high- T_c superconductor La_2CuO_4 , ferrite insulator Fe_2O_3 , pnictide with metal-insulator transition FeSb_2 and metal CrSb , chalcogenide semiconductor MnTe and (semi)metal VNB_3S_6 , CoNb_3S_6 , silicide metal Mn_5Si_3 , and organic insulator $\kappa\text{-Cl}$. One should also note that altermagnetism can occur in structures with inversion symmetry (e.g., rutiles), or without inversion symmetry (e.g., VNB_3S_6 or CoNb_3S_6).

Magnetic insulators

The spintronic applications described so far typically depend on conducting materials where the spin information is carried by delocalized electrons. However, spin information can be generated, transported and manipulated through SWs, or their quanta magnons, a field that has been coined as magnonics (Stamps et al., 2014; Sander et al., 2017; Demidov et al., 2017; Rana and Otani, 2019; Barman et al., 2021; Pirro et al., 2021; Chumak et al., 2022). In this regard, spin transport can be activated between localized electrons. When considering only magnetic insulators, the term spin insulatronics has also been used (Brataas et al., 2020). As a matter of fact, the best spin conductors are insulators. The crucial distinction in the information carrier can lead to ground-breaking changes in device designs and new applications. This necessarily introduces novel research directions with their own challenges and opportunities as described below.

Magnetic insulators are typically governed by indirect antiferromagnetic superexchange, which results in either antiferromagnetic or ferrimagnetic order. In the former, the magnetizations of the sublattices are fully compensated, leading to overall zero magnetization, while in the latter the compensation is not complete, leading to a net magnetization. It is however possible to modify the properties of one or both sublattices of an AFM, for example by doping, to achieve a net magnetization. In addition, their characteristic SW dispersion relation can be tuned with external magnetic field; the SW frequencies and wavelengths vary from GHz to THz and from μm to nm, respectively (Gurevich and Melkov, 2020; Chumak et al., 2022). As already mentioned in Section “Antiferromagnets and altermagnets” the fast dynamics of AFMs represent an advantage for fast spintronic devices.

Among magnetic insulators, the material that has been investigated the most is yttrium iron garnet $\text{Y}_3\text{Fe}_5\text{O}_{12}$ (YIG), which is a ferrimagnetic insulator. YIG has the lowest known magnetic dissipation in nature and is characterized by an extremely small magnetic damping constant. Other materials include NiO , CoO , $\alpha\text{-Fe}_2\text{O}_3$, CrO_2O_3 , BiFeO_3 and other garnets such as $\text{Tm}_3\text{Fe}_5\text{O}_{12}$ (TmIG). Long-range spin transport has been reported in $\alpha\text{-Fe}_2\text{O}_3$. Domain wall motion and the observation of skyrmions have been investigated in TmIG/Pt bilayers at room temperature, and there are reports of skyrmions in multiferroic Cu_2OSeO_3 at low temperature. In this section, several research directions are introduced that attempt to capitalize on the characteristics of magnetic insulators to achieve significant technical improvements.

Magnons as carriers of information

Spin devices with magnetic insulators capitalize on the transport properties of magnons. Here best performances are achieved in materials supporting long propagation distance for SWs. The propagation distance is here relative to their group velocity, which turns out to be slow for low-energy spin excitations (of the order of sound velocity) allowing the development of compact solutions. The concept is available in the form of (i) analogic devices such as filters or delay lines or (ii) digital devices, which exploits the ondulatory character of magnons. The later effort aims at developing Boolean functions based on wave interference to calculate the output with much smaller footprint compared to their semiconductor counterparts. More recent topics that have emerged in the field of magnonics apply to neuromorphic (Christensen et al., 2022) or bio-inspired computations, which rely on the coupling between long wavelength SWs to solve efficiently certain class of hard problems such as pattern recognition.

Among the key advantages offered by magnons are their very large energy tunability via an external magnetic field enabling a wide control range of operating frequencies spanning a spectral window from GHz to THz (Brataas et al., 2020). Another key advantage is their scalability down to the nanometer level and their wide tolerance to external settings such as the temperature of the device, which can operate from cryogenics values to hundreds of Celsius or under irradiation. The current research topics in this area are advanced computational methods such as logic or artificial intelligence (Barman et al., 2021; Chumak et al., 2022). For example, using magnonics, one can envision a neural-network implementation that is qualitatively different from all existing proposals. Instead of designing and structuring individual nonlinear elements (neurons) and their interconnections (synapses) in real space, one can propose a different paradigm in which these elements are constructed in reciprocal or k -space of large dimensionality. One can then imagine realizing the concept of hyper-connectivity using SWs as neurons. The key property of magnetization dynamics is its strong nonlinearity, which, when coupled with geometrical effects and external stimuli like applied fields and currents, translates into two useful features for neural networks: (i) nonlinear interactions through exchange and dipole-dipole interactions can potentially couple all SW modes together, thereby creating high connectivity, and (ii) the strength of the coupling depends on the population of each k mode, thereby allowing for synaptic weights to be modified dynamically. The breakthrough concept is that real-space structuration is not necessary to achieve hyper-connectivity or reconfigurable synaptic weights. One of the major roadblocks for SW computing is the difficulty to efficiently couple electrically to a magnon in an insulator. For short wavelength SWs, the inductive coupling introduces significant insertion losses that are critically detrimental to the overall energy efficiency of the device, in particular at high frequencies. The solution seems to be the exploitation of an interconversion process between the spin and charge degrees of freedom, which enables the electrical control of SWs amplitude in insulators, via the spin transfer effect from an adjacent metal electrode.

Non-linear magnonic devices

A second research direction is the exploitation of the strong propensity of magnons to behave non-linearly, which could be exploited to create spin diodes, spin amplifiers or spin rectifiers of microwave signals (Brataas et al., 2020). Reducing the magnetic damping in a magnetic material allows for a drastic decrease of the non-linear threshold for parametric instabilities. In materials with ultra-low damping, a 0.1% change in thermal occupation is usually enough to drive the magnetization dynamics into the nonlinear regime. These non-linear effects can be very useful for various nonlinear applications such as rectification, amplification, asymmetric transport (spin diode effect), mixing or generation of chaos.

Again, the spin transfer effect enables the electrical control of μ_M , the magnon chemical potential, via an electrical current in an adjacent metal electrode. The anticipated benefit is the realization of a new form of solid state spin diode obtained by shifting μ_M relative to E_g , the energy gap in the magnons' band diagram. The level-arm is set here by the magnetic damping parameter, α_{LLG} : the smaller is the damping the larger are the shifts of μ_M produced electrically.

In this respect, the ferrimagnet YIG, with the lowest known magnetic damping, is expected to lead to the highest benchmark in nonlinear transport performance. While the spin diode effect in laterally confined geometries is rather well understood, its generalization to extended thin films has so far been elusive. The corresponding difficulty is the collective dynamics that emerges inside the magnon continuum, when the level splitting between eigen-modes becomes smaller than their linewidth.

Interaction of magnons with other carriers of information

A third research direction addresses the coupling between SWs to other waveforms and carriers of information (Lachance-Quirion et al., 2019; Li et al., 2020; Zare Rameshti et al., 2022). The aim is to achieve strong coupling to preserve the coherence, which means that the phase information is preserved during the interconversion process. Such an interconversion is desirable to extend the quantum functionalities of the spin state. The figure of merit is set here by the cooperativity, which defines when the coupling strength becomes greater than the geometric mean of the coherence time of the different waveforms. In this regard, the insulating magnetic garnets are the best choice with respect to the magnon lifetime.

While optimizing the interaction by maximizing the overlap integral of two spatio-temporal patterns is primarily a design issue, diminishing the dissipation in a magnet is a complex task, which requires know-how in material research and growth technology. YIG combines extremely low magnetic damping, excellent acoustic attenuation ($10\times$ better than quartz), and optical transparency. YIG thus provides the best possible coherent interlink between magnons, phonons, and both microwave and optical photons (Lachance-Quirion et al., 2019; Li et al., 2020). The experiments performed on millimeter-size YIG single crystals have demonstrated strong coupling at microwave frequencies between magnon, photon and phonons. This encompasses the extension to the quantum regime of the magnon-photon coupling at low temperature (Lachance-Quirion et al., 2019). Devices coupling a YIG sphere to a superconducting quantum circuit have demonstrated the ability to detect a single magnon at ultra-low temperature (Zare Rameshti et al., 2022). It has been also reported that high cooperativity between two macrospins can be achieved due to magnon-phonon coupling. Acoustic phonons in garnets are likely the best waveform to couple coherently distant spins. This is because mechanical vibrations at microwave frequencies can benefit from ultralow damping in such crystals. Interestingly one can control the parity of the magnon-phonon coupling in these systems, where resonances with odd/even phonon modes correspond to out-of-phase/in-phase lattice displacements at the position of the macrospin, leading to bright/dark states in response to uniform microwave magnetic fields, respectively. While such experiments have been performed at room temperature, quantum information exchange and distant entanglement of magnons, phonons, and microwave photons could occur at low temperature. All these are crucial steps in the quest of developing integrated solutions in quantum technologies, in which long-range transport of coherent information between distant quantum gates is a key technological challenge.

These findings establish fruitful connections between the fields of magnetism and quantum information. The next step is to establish this connection with much smaller objects (ideally in the micron-size). The expected difficulties are a degradation of the damping once the size of the sample shrinks. Additional relaxation processes are expected to emerge due to the increased influence of various crystal imperfections and surface defects. In the case of elastic modes, it might be necessary to suspend the oscillating body to isolated from the substrate. However, the reasons for the deterioration of the damping in small structures are still poorly understood. Experiments with magnetic garnets of decreasing size, composition and growth/patterning methods are required to optimize magnonic devices in which large coherence times are preserved.

Conclusion

Spintronics is a very lively field, which has experienced many major advances in the last 35 years thanks to the synergy between industry and academic laboratories, where a significant proportion of novel materials and devices has been developed. Several generations of hard disk drives, sensors and non-volatile memories have adopted fundamental concepts such as GMR, TMR, spin filtering and STT in short time spans (Fig. 2). STT-MRAM products are already in the market and have proven potential for replacing various existing memories, where non-volatility, endurance and speed are required. The discovery of the SHE in metals has triggered fundamental research leading to the development of SOT-MRAM, which could be suitable for fast caches and embedded memories. VCMA, optical switching, also in combination with STT, SOT and orbital phenomena, could expand the technological opportunities

for beyond-CMOS memories and devices. AFMs and altermagnets could add functionalities for dense memories and high-frequency electronics bridging the THz gap, while insulator spintronics may open the way for low-power information transport and logics.

This chapter has discussed the main device concepts and applications from a material perspective. Although, it cannot cover the entire field, it provides an overview of some of the most relevant families of practical materials including several that are being intensively investigated to overcome future technological challenges such as transition-metal alloys, Heusler compounds, 2D materials, antiferromagnets and altermagnets, and insulators. However, this list is not exhaustive, other materials such as organic magnets or semiconductors, which have been an active area of research in recent years, are not discussed. Materials for quantum information processing using single electron spins or magnetoelectric interactions for magnetic logics are also not addressed.

Research on these emerging topics and materials for spintronics will only grow in the future. Many technical challenges remain for applications, but a vast number of opportunities are envisioned. Synchronized MTJ devices can provide novel solutions for neuromorphic computing. AFM/FM bilayers present a memristor behavior like the multilevel SOT switching in bulk AFMs, which could also be relevant for neuromorphic computing. This behavior is attributed to a progressive current-induced switching of different magnetic domains in the FM, which are pinned by the exchange coupling with the AFM. Considering that magnons behave as bosons, the predicted emergence of new condensed magnon phases in insulators, such as a superfluid phase produced by a Bose-Einstein condensate, could lead to novel coherent transport phenomena.

Progress will continue to be achieved by developing novel functional materials, heterostructures and device architectures, followed by the implementation of compatible industrial processes. For example, for any technology using vdW materials to be successful, large-scale production and subsequent integration into CMOS-compatible production lines will be required. Approaches relying on chemical vapor and physical deposition are being developed for growth, which likely must be combined with reliable transfer techniques. Optimizing these processes for each material and application is crucial and must be accompanied with the development of dedicated process monitoring and metrology tools. The emergence of new material simulation methods, including machine learning and artificial intelligence, to search and identify specific functionalities could significantly accelerate the adoption of fundamental concepts into novel technologies.

Abstract

The spin-galvanic effect is a transfer of the non-equilibrium electron spin polarization into a translational motion of free charge carriers. This spin-to-current conversion is allowed by the symmetry of the gyrotropic point groups which make no difference between some components of polar and axial vectors. We consider different mechanisms of the spin-galvanic effect, particularly, the kinetic and relaxational, that are determined by instantaneous values of the spin polarization and its time derivative, respectively. The gyrotropic symmetry allows as well the inverse spin-galvanic effect, or current-to-spin conversion. We review the basic experiments on the direct and inverse spin-galvanic effects which can be observed in various gyrotropic semiconductor systems and ferromagnet/semiconductor bilayers, at metal surfaces or interfaces and surfaces of topological insulators.

Key points

The focus of this chapter lies on the interconnection between the non-equilibrium electron spin polarization and the electric current in gyrotropic systems. The interconnection is realized in the spin-galvanic effect and its reversal. In short, the spin drives current, and the current drives spin.

Introduction

Non-equilibrium spin dependent phenomena in solids and solid structures lie at the heart of the fast-growing field of spintronics, or spin electronics. Among plethora of the related concepts and ideas, the interconnection between the electron spin polarization and the electric current has attracted a lot of research interest both theoretical and experimental: in semiconductors or metals belonging to the gyrotropic point groups, a non-equilibrium homogeneous spin polarization induces an electric current and vice-versa. The former phenomenon is called the spin-galvanic effect (SGE) and the latter the inverse spin-galvanic effect (inverse SGE).

The ability of non-equilibrium spin in gyrotropic media to produce the charge current (SGE), was proposed by Ivchenko et al. (1989). Experimentally this effect has been first observed in GaAs quantum wells by spin injection under circularly polarized optical excitation by Ganichev et al. (2002). The inverse effect of current-to-spin conversion (inverse SGE) was predicted long ago

(Ivchenko and Pikus, 1978), the theory was extended by Vas'ko and Prima (1979), Aronov and Lyanda-Geller (1989), and Edelstein (1990). Further studies have shown that both the direct and inverse effects can be observed in various semiconductor systems (for review see Ivchenko and Ganichev, 2017), at metal surfaces or interfaces (Rojas Sánchez et al., 2013; Shen et al., 2014a), ferromagnet/semiconductor bilayer (Skinner et al., 2015), and surfaces of topological insulators (Shiomi et al., 2014; Mellnik et al., 2014). It should be noted that the inverse SGE is sometimes referred to as the Edelstein or Rashba–Edelstein effect and consequently the SGE to as the inverse Rashba–Edelstein effect.

Phenomenological description

In a homogeneous system of free charge carriers with a non-equilibrium spin-state occupation, but equilibrium energy distribution within each spin branch, the spin relaxation may be accompanied by generation of an electric current. Phenomenologically, the current density j and spin density S are related by a second-order tensor

$$j_\lambda = Q_{\lambda\mu} S_\mu. \quad (1)$$

More exactly, Q is a pseudotensor because it couples a conventional polar vector with a pseudovector. It is nonzero for point groups that allow optical activity or gyrotropy. The gyrotropic point-group symmetry makes no difference between at least some components of polar vectors, like current or electron momentum, and axial vectors, like a magnetic field or spin. Note that, among 21 bulk crystal classes lacking inversion symmetry, 18 groups are gyrotropic. Three nongyrotropic noncentrosymmetric classes are T_d , C_{3h} and D_{3h} . The symmetry of 2D systems is described by the layer groups, or three-dimensional groups with two-dimensional translations. There are 18 noncentrosymmetric layer point groups, among them 16 are gyrotropic and allow the SGE.

In Eq. (1), a repeated subscript is understood to imply summation over the range of this subscript. In a bulk semiconductor or superlattice the index λ runs over all three Cartesian coordinates x , y , z . In two-dimensional (2D) systems the free-carrier motion along the growth direction is quantized and the index λ enumerates two in-plane coordinates. In quantum wires or nanotubes the free movement is allowed only along one principal axis of the structure, and the coordinate λ is parallel to this axis. On the other hand, the spin polarization S can be arbitrarily oriented in space and, therefore, the index μ runs over all the three coordinates x , y and z .

In spite of the terminological resemblance, spin-to-current transfer fundamentally differs from the spin Hall effect which means the generation of a pure spin current transverse to the charge current, causes spin accumulation at the sample edges, is described by the third-rank tensor and does not require gyrotropy.

The spin-to-current conversion suggests its reciprocal phenomenon, namely, current-induced spin polarization, or the inverse SGE, described by

$$S_\mu = R_{\mu\lambda} j_\lambda. \quad (2)$$

Inversely to Eq. (1), the tensor R couples a pseudovector to a vector and also has nonzero components solely in the gyrotropic systems.

Mechanisms of the spin-galvanic effect

Microscopic mechanisms of the direct and inverse SGEs in 2D nanostructures are mostly based on the spin-orbit interaction described by the Hamiltonian

$$\mathcal{H}^{(1)} = \beta_{ij} \sigma_i k_j, \quad (3)$$

where k is the charge-carrier wave vector and σ_i are the Pauli spin matrices. Sometimes it is convenient to introduce the effective Larmor frequency with the components $\Omega_{k,i} = 2\beta_{ij}k_j/\hbar$ and rewrite the Hamiltonian (3) as $\hbar\Omega_k \sigma/2$. The coefficients β_{ij} form a pseudotensor subjected to the same symmetry restriction as the spin-galvanic tensors Q and R . Moreover, one can expect the following proportional relationship between the photocurrent and the components of tensor β

$$j_i \propto \beta_{ii} S_i, \quad (4)$$

which can be confirmed by microscopic considerations.

Kinetic mechanism

The non-equilibrium spin polarization S in Eq. (1) induces an electric current due to the following mechanism. The spin-orbit interaction (3) splits the electron energy band into spin subbands in the k space. Taking into consideration the interaction, for example, in the form $\beta_{yx}\sigma_y k_x$, we obtain two subbands shifted along k_x by $\pm k_0$ with k_0 being $\beta_{yx}m^*/\hbar^2$, where m^* is the electron effective mass. A nonzero value of S_y means that one of the subbands is more populated than the other. The Elliot–Yafet spin

Fig. 1 (A) Microscopic origin of the kinetic spin-galvanic current. ε is the electron energy taking into account spin-orbit splitting, k_x is the x -component of the electron wave vector. Left panel: One-dimensional sketch. The spin branch $|+1/2\rangle_y$ is preferentially occupied, $S_y > 0$. Bent arrows show the spin-flip scattering processes. Two transitions denoted by solid arrows have the same rates and do not yield a current. The transitions sketched by dashed arrows yield an asymmetric filling of the subbands and, hence, a current flow. Right panel: The spin-flip transitions in the two dimensions at scattering angle θ different from 0. (B) Current-induced spin polarization due to spin-flip scattering. Due to the drift in the electric field $\mathbf{E}$ applied in the positive direction of the x axis, the electron distribution within each spin branch is shifted along k_x in the same way so that the energy subbands still are equally populated. The spin-flips $-1/2 \rightarrow 1/2$ and $1/2 \rightarrow -1/2$ shown by broken bent arrows have different transition rates and, as a result, a nonzero spin polarization S_y is built up. After Ganichev SD and Prettl W (2003) Spin photocurrents in quantum wells. *Journal of Physics: Condensed Matter* 15: 935.

relaxation causes an intersubband flow of electrons. Because of the spin splitting the spin relaxation quantum transitions are asymmetric in the $\mathbf{k}$ -space and give rise to an antisymmetric correction to the electron distribution function $f_{\mathbf{k}}$ which is nothing more than a flow of the electron charges, i.e. an electric current. This mechanism is termed kinetic.

Fig. 1A illustrates the generation of a spin-galvanic current in a 2D structure presented by Ganichev and Prettl, (2003). The spin-orbit interaction $\sigma_y k_x$ splits the conduction band into two parabolas with the spin $s_y = \pm 1/2$. Moreover, we take into account spin-dependent electron scattering by static defects (or acoustic phonons) in the form (Averkiew et al., 2002)

$$V_{\mathbf{k}\mathbf{k}'} = V_0 + V_{ij}\sigma_i(k'_j + k_j), \quad (5)$$

where $\mathbf{k}$ and $\mathbf{k}'$ are the initial and scattered wave vectors, V_0 and V_{ij} are scalar functions of $\mathbf{q} = \mathbf{k}' - \mathbf{k}$. Let the spin branch $|1/2\rangle_y$ be more populated (dark-gray) as compared with the spin $|-1/2\rangle_y$ (light-gray). As long as the carrier distribution in each subband is symmetric around the subband minimum point no current flows. The electrons are scattered from the more populated subband, e.g., the subband $|+1/2\rangle_y$, to the less populated subband $|-1/2\rangle_y$. Note that the scattering changes both k_x and k_y components of the electron wave vector as shown in the right part of Fig. 1A by dashed arrows. However, the one-dimensional sketch conveys the interpretation in a simpler and clearer way. Four different spin-flip scattering events are depicted in the left part of Fig. 1A by bent arrows. According to Eq. (5) the spin-flip scattering rate depends on values of the involved wave vectors. One can show that the spin-flip transitions shown by solid arrows in Fig. 1A have the same rates. However, two other scattering processes shown by broken arrows are inequivalent and generate an asymmetric carrier distribution around the subband minima in both subbands. This asymmetric population results in a current flow along the x -direction.

A microscopic model of the current-induced spin polarization is sketched in Fig. 1B. In equilibrium, the electron distribution in each spin branch is symmetric with respect to the corresponding point $k_x = \pm k_0$. If an external electric field $\mathbf{E} \parallel x$ is applied, the electrons drift in the direction of the resulting force, the distribution within each spin branch becomes asymmetric but the net spin polarization S_y does not appear. Now let us switch in the spin relaxation. As in Fig. 1A the processes indicated by broken lines have different scattering rates. Due to the asymmetric distribution along k_x and the dependence of the matrix elements (5) on wave vectors, the spin-flip relaxation processes $\pm 1/2 \rightarrow \mp 1/2$ result in an appearance of the mean spin polarization.

Relaxational mechanism

A different contribution to the current j arises in the so-called relaxational mechanism for time dependent spin polarization $S(t)$. In this case it is enough to take into account the spin-orbit interaction (3) and the electron momentum relaxation the current to get

$$j_z = 2e\tau_p \frac{\beta_{\mu\lambda}}{\hbar} \frac{dS_\mu}{dt}, \quad (6)$$

where e is the electron charge and τ_p is the momentum relaxation time. This means that, in the frequency domain representation of j and S , the relaxational spin-galvanic tensor $Q_{\lambda\mu}^S(\omega)$ is proportional to $-i\omega$ and given by $-2i\omega e\tau_p \beta_{\mu\lambda}/\hbar$. The relaxational mechanism can also be understood in terms of the coherent trembling motion (Zitterbewegung) of spin-polarized electrons in an external magnetic field, $\mathbf{B}$. We take $\mathbf{B}$ parallel to the x axis in which case the Zeeman Hamiltonian has the form $(\hbar/2)\omega_L\sigma_x$ where $\omega_L = g\mu_B B/\hbar$ is the Larmor frequency, g is the electron Landé factor (or g factor) and μ_B is the Bohr magneton. The trembling motion originates from the fact that, in quantum mechanics, the electron velocity is not a conserved quantity in the presence of spin-orbit interaction. Taking into account the linear- $\mathbf{k}$ term (3) and the Zeeman Hamiltonian we have for the electron velocity $v_x = \hbar k_x/m^* + (\beta_{yx}/\hbar)\sigma_y$, and then obtain for the acceleration operator $\dot{v}_x = -(\beta_{yx}/\hbar)\omega_L\sigma_z$. Including the electron momentum scattering as a "friction force" we arrive at the following equation for the average electron velocity (Tarasenko et al., 2018)

$$\frac{d\bar{v}_x}{dt} + \frac{\bar{v}_x}{\tau_p} = -\frac{2\beta_{yx}}{\hbar} \omega_L s_z(t),$$

where $s_z = S_z/n_e$ is the spin polarization per particle and n_e is the electron density. In the fast scattering limit, $\omega_L \tau_p \ll 1$, the time derivative $d\bar{v}_x/dt$ is negligible and the oscillating current is given by Eq. (6) because $-\omega_L s_z = ds_y/dt$. The relaxational mechanism can be related to the time-dependent electric current induced by an ac magnetic field $\mathbf{B}$ and described by $j_i(\omega) = -i\omega\alpha_{i\mu}B_\mu(\omega)$. Indeed, in the Fourier transform of Eq. (6), one can substitute $-i\omega(1 - i\omega\tau_s)^{-1}S_\mu^{(0)}(\omega)$ instead of dS_μ/dt , where τ_s is the spin relaxation time, $S^{(0)} = -(g\mu_B\mathbf{B}/4\bar{e})n_e$, and $\bar{e}$ is the characteristic electron energy equal to the Fermi energy at low temperature and the thermal energy $k_B T$ at high temperature T (k_B is the Boltzmann constant). It follows then that $\alpha_{i\mu}$ is proportional to the constant $\beta_{i\mu}$ of the spin-orbit interaction. The principle of symmetry of the kinetic coefficients allows one to relate the tensor of the inverse SGE with the tensor α as follows $R_{i\mu} = \alpha_{i\mu}(\sigma/g\mu_B)$, where $\sigma = e^2 n_e \tau_p / m^*$ is the electron conductivity. It is worth to note that, due to the Maxwell equation, $\text{curl } \mathbf{E} = -\partial \mathbf{B} / \partial t$, an allowance for the magnetization current, in fact, doubles the current induced by the magnetic field (Levitov et al., 1985).

Mechanism due to the spin injection

An additional contribution to the relaxational and kinetic spin-to-current conversions also comes from a continuous spin injection source. The spin generation rate $G^{(s)}$ induces an electric current described by Eq. (6) where the time derivative of spin polarization is replaced by $-G^{(s)}$, i.e.,

$$j_i = -2e\tau_p \frac{\beta_{i\mu}}{\hbar} G_\mu^{(s)}. \quad (7)$$

It follows then that, under pulsed spin generation, one should use Eq. (6) whereas, in the steady-state regime, the current is given by Eq. (7). In case of a prolonged time-dependent generation, the both currents (6) and (7) should be combined.

Burkov et al. (2004), have derived a microscopic linear response theory and proposed an electrical spin injection experiment where a voltage will develop between two ferromagnetic contacts if a spin-polarized current is injected into a 2D electron gas.

Optically induced spin-galvanic effect

Basic experiments

The uniform non-equilibrium spin S can be achieved by both optical and non-optical methods, e.g., by the spin pumping, see the next section. Optical orientation of electron spins is obtained in both bulk and low-dimensional semiconductor systems applying circularly polarized light of the wide spectral range from visible to far-infrared. It is caused by a transfer of the photon helicity to the spin of free carriers and has been demonstrated for interband absorption, resonant optical transition between size-quantized subbands and free carrier absorption. Usually, the optically excited SGE is observed simultaneously with the circular photogalvanic effect (CPGE) which is phenomenologically described by (Ivchenko and Pikus, 1978)

$$j_i = IP_c \gamma_{i\mu} n_\mu, \quad (8)$$

where I , P_c and $\mathbf{n}$ are the light intensity, degree of circular polarization and unit vector pointing in the direction of the exciting beam. Since the spin-galvanic and photogalvanic pseudotensors, $Q_{i\mu}$ and $\gamma_{i\mu}$, are subjected to the same symmetry restrictions they do not allow an easy experimental separation and an indivisible mixture of both effects may be observed. Nevertheless, microscopically these two effects are definitely inequivalent. Indeed, the steady-state SGE is caused by asymmetric spin-flip scattering of spin polarized carriers and determined by the spin relaxation processes. If spin relaxation is absent the spin-galvanic current vanishes. In contrast, the CPGE is a result of selective photoexcitation of carriers in the $\mathbf{k}$ -space with circularly polarized light due to optical selection rules, it is independent of the spin relaxation if $\tau_s \gg \tau_p$.

Evidently, these two effects can behave differently upon variation of the microscopic material properties which allows their experimental separation. For instance, a dominating contribution of the SGE has been demonstrated for intersubband optical transitions excited under the oblique light incidence in n -type zinc-blende-lattice quantum wells of the C_{2v} symmetry applying qualitatively different spectral dependence of the spin-galvanic and circular photogalvanic effects (Ganichev et al., 2003). Two other methods are more general and can be applied in most cases. In one of them the effects can be separated in time-resolved measurements. Indeed, after removal of light or under pulsed photoexcitation the circular photogalvanic current decays within the momentum relaxation time τ_p whereas the spin-galvanic current decays with the spin relaxation time. Another method provides, on the one hand, a uniform distribution in spin subbands and excludes, on the other hand, the CPGE. It is based on the use of optical excitation under normal incidence and the assistance of an external magnetic field to achieve an in-plane polarization in (001)-grown low-dimensional structures (Ganichev et al., 2002).

The geometry of experiment depicted in Fig. 2 allows one to observe the SGE under steady-state photoexcitation and exclude the CPGE. The circularly polarized light is incident normally to the interface plane (001) of the quantum well, the light absorption yields a steady-state spin polarization S_{0z} in the z direction proportional to the light intensity. The symmetry of (001)-grown quantum wells forbids generation of a current proportional to the normal component of S . To obtain an in-plane component of the

Fig. 2 Spin-galvanic current j_x as a function of magnetic field $\mathbf{B} \parallel x$ for normally incident right-handed (open circles) and left-handed (solid circles) circularly polarized radiation. Solid and dashed curves are fitted after Eq. (9). Inset shows optical scheme of generating a uniform in-plane spin polarization which causes a spin-galvanic current. Electron spins are oriented normal to the quantum well plane by circularly polarized radiation and rotated into the plane by the Larmor precession in the in-plane magnetic field. After Ganichev SD, Ivchenko EL, Bel'kov VV, Tarasenko SA, Sollinger M, Weiss D, Wegscheider W, Prettl W (2002) Spin-galvanic effect. *Nature* 417: 153–156.

spins, necessary for the SGE, a magnetic field $\mathbf{B} \parallel x$ is applied. Due to Larmor precession a non-equilibrium spin polarization S_y is induced,

$$S_y = -\frac{\omega_L \tau_{s\perp}}{1 + (\omega_L \tau_s)^2} S_{0z}, \quad (9)$$

where $\tau_s = \sqrt{\tau_{s\parallel} \tau_{s\perp}}$ and $\tau_{s\parallel}$, $\tau_{s\perp}$ are the longitudinal and transverse electron spin relaxation times, ω_L is the Larmor frequency. The spin-galvanic current $\mathbf{j}$ appears in the x direction. In accordance with Eq. (9) the current j_x is an odd function of both the magnetic field and the light circular polarization and exhibits nonmonotonous variation with the magnetic field.

Determination of the SIA/BIA spin splitting ratio

An important application of the spin-galvanics was addressed by Ganichev et al. (2004b). It was demonstrated that angular dependent measurements of spin photocurrents allow one to separate the different contributions to the spin-orbit Hamiltonian (3). To be specific we show this method on example of (001)-oriented GaAs quantum wells for which the Hamiltonian (3) for the first subband reduces to

$$\mathcal{H}^{(1)} = \alpha(\sigma_x k_y - \sigma_y k_x) + \beta(\sigma_x k_x - \sigma_y k_y). \quad (10)$$

Here x, y are the crystallographic axes $[100]$ and $[010]$, the parameters α and β result from the structure-inversion and bulk-inversion asymmetries, abbreviated SIA and BIA, respectively. The first and second contributions to the Hamiltonian (10) are often called the Rashba and Dresselhaus terms. Note that, in the coordinate system $x' \parallel [1\bar{1}0]$, $y' \parallel [110]$, the matrix $\mathcal{H}^{(1)}$ gets the form

$$\beta_{x'y'} \sigma_{x'} k_{y'} + \beta_{y'x'} \sigma_{y'} k_{x'}$$

with $\beta_{x'y'} = \alpha + \beta$, $\beta_{y'x'} = -\alpha + \beta$. In Fig. 3, we show the direction of eigen spins at constant energy lines for different (A) and equal (B) strengths of BIA and SIA spin-orbit interactions presented by Ganichev and Golub, (2014). If the strengths of BIA and SIA coincide, then the 2D band structure consists of two revolution paraboloids with revolution axes symmetrically shifted in opposite directions with respect to $\mathbf{k} = 0$, see Fig. 3C. The case of only Rashba or Dresselhaus spin-orbit coupling is illustrated in Fig. 3D.

Fig. 3 The distribution of electron spin orientations at the constant energy lines calculated after Eq.(10): (A) for the general case of different strengths of the BIA and SIA terms, $\alpha \neq \beta$, and (B) for $\alpha = \beta$. Panels (C) and (D) show schematic 2D band structure for equal strength of the BIA and SIA terms in the Hamiltonian and for zero SIA/BIA, respectively. Note, that whereas the spin splitting in the latter case looks identical for pure SIA and BIA, the relative directions of the spin and electron momentum are different. After Ganichev SD and Golub LE (2014) Interplay of Rashba/Dresselhaus spin splittings probed by photogalvanic spectroscopy – A review. *Physica Status Solidi B* 251: 1801–1823.

According to Eq. (4) the current components j_x, j_y are proportional, respectively, to β_{yx} and β_{xy} and, therefore, angular dependent measurements of spin-galvanic current allow one to separate the SIA and BIA linear- k terms. By mapping the magnitude of the photocurrent in the quantum well plane the ratio of both terms can directly be determined from experiment and does not rely on theoretically obtained quantities. For the particular Hamiltonian (10) the relation between the photocurrent and spin directions can be conveniently expressed in the following matrix form.

$$\begin{pmatrix} j_x \\ j_y \end{pmatrix} \propto \begin{bmatrix} \beta & -\alpha \\ \alpha & -\beta \end{bmatrix} \begin{pmatrix} S_x \\ S_y \end{pmatrix}. \quad (11)$$

Experimentally the above method has been applied to study BIA/SIA terms in GaAs, InAs, SiGe and a number of other semiconductor low-dimensional materials. These experiments also demonstrate that growth of structures with various delta-doping layer position accompanied by experiments on SGE makes possible a controllable variation of the structure inversion asymmetry and preparation of samples with equal SIA and BIA constants or with a zero SIA constant.

Spin-galvanic effect in transport experiments

In transport measurements the SGE has been first observed by Rojas Sánchez et al. (2013), in Bi/Ag Rashba interface. The non-equilibrium spin polarization at the interface has been obtained using spin pumping. Fig. 4 shows the experimental arrangement. A vertical pure spin current J_{SH} , with opposite dc spin-up and spin-down flows and the spin polarization along the x axis, is injected from the NiFe layer into the Ag layer using a spin pumping effect operated by the ferromagnetic resonance (FMR).

The SGE converts the non-equilibrium spin at the interface into a dc electric current carried along y by the interfacial electron system subject to the Rashba spin-orbit interaction. In the situation of an open circuit shown in Fig. 4 this process gives rise to a dc voltage V . The electric current J and the voltage V are related by

$$J = \frac{aV}{R_S l},$$

where a , l and R_S are, respectively, the width, length and sheet resistance of the sample. Fig. 4B shows the derivative of the ferromagnetic absorption and the corresponding magnetic field dependence of J at the FMR for a sample with a Bi/Ag layer below NiFe.

The drift-diffusion theory derived by Shen et al. (2014a, b), is applicable to a broad variety of spin-charge transport phenomena, it describes well the experimental findings including the interpretation of the experiment by Rojas Sánchez et al. (2013).

Current induced spin polarization

Current induced spin polarization, or inverse SGE, was first observed on a chiral tellurium single crystal by Vorob'ev et al. (1979). Above we considered the case of small spin-orbit splitting, $|\beta_{ij}k_j| \ll \hbar/\tau_p$ (the collision-dominated regime). In Te crystals the

Fig. 4 (A) Scheme of the NiFe/Ag/Bi samples under ferromagnetic resonance (FMR). The radio frequency field is applied along y , and the dc magnetic field B along x . J_{SH} is the vertical dc spin current injected into the Ag/Bi interface states (back flow included), and converted into a horizontal dc charge current J by the SGE. In an open circuit situation J is balanced by the current associated to the dc voltage V . (B) FMR spectrum dX''/dB (derivative of the ferromagnetic absorption) and corresponding field dependence of the current J derived from the dc voltage V for NiFe(15)/Ag(5)/Bi(8) sample where numbers in brackets indicate layer thicknesses in nanometers. From Rojas Sánchez JC, Viva L, Desfonds G, Gambarelli S, Attané JP, De Teresa JM, Magén C, and Fert C (2013) Spin-to-charge conversion using Rashba coupling at the interface between non-magnetic materials. *Nature Communications* 4: 2944.

spin-orbit splitting $2\sqrt{\Delta_2^2 + (\beta k_z)^2}$ between the nondegenerate hole subbands H_4 and H_5 exceeds by far the uncertainty $\hbar/\tau_p$. Here Δ_2 and β are the band parameters, z is the trigonal axis. Moreover, the holes occupy only the lowest valence subband with the energy dispersion

$$\varepsilon_k = Ak_z^2 + B(k_x^2 + k_y^2) - \sqrt{\Delta_2^2 + \beta^2 k_z^2} + \Delta_2.$$

The hole magnetization along z in the state $\mathbf{k}$ is given by

$$m_{k,z} = -\frac{1}{2} \frac{g\mu_B \beta k_z}{\sqrt{\Delta_2^2 + \beta^2 k_z^2}},$$

where g is the hole longitudinal g factor. Because of the lifted degeneracy the hole group velocity and angular momentum are strongly coupled as follows

$$v_{k,z} = \frac{2}{\hbar} \left(Ak_z + \frac{\beta m_{k,z}}{g\mu_B} \right).$$

This equation allows one, in the simplest way, to conceive the spin-to-current and current-to-spin conversions: a shift of the distribution function in the $\mathbf{k}$ space directly causes a change in the average angular momentum of holes and vice versa. Similarly to the Faraday effect, the current-induced magnetization can be probed by linearly polarized light via rotation of its polarization plane during propagation through the sample.

Fig. 5 shows the experimental arrangement and spectral dependence of the inverse SGE presented by Shalygin et al. (2012). In the inset θ is the angle of rotation due to the natural optical activity, and φ is an additional angle of rotation induced by the electric current j_z . It has been shown that the experimentally observed spectral dependence of the current-induced optical activity is adequately described in the framework of the existing theoretical model of Te band structure.

In bulk tellurium current-induced spin polarization is a consequence of the “camel back” valence band structure characterized by a strong spin-orbit splitting between the two upper subbands and by hybridized spin-up and spin-down states. In zinc-blende-lattice based quantum wells this effect arises in the opposite case of the collision-dominated regime as was shown theoretically by Vas’ko and Prima (1979), Aronov and Lyanda-Geller (1989), and Edelstein (1990). The inverse SGE in 2D semiconductor systems was almost simultaneously and independently observed by Ganichev et al. (2004a), Kato et al. (2004), and Silov et al. (2004). The experiments include the range of optical methods such as the Faraday rotation and linear-circular dichroism in transmission of terahertz radiation, time resolved Kerr rotation and polarized luminescence. We emphasize that current-induced spin polarization as well as the SGE were observed even at room temperature.

Fig. 5 Spectral dependencies of the current induced optical activity ($-\gamma$, open circles) and the natural optical activity (θ/L , closed circles) in tellurium at $T = 77$ K (experiment), the solid line corresponds to the theoretical calculation. Dots are experimental data by Shalygin et al. (2012), and triangles by Fukuda et al. (1975). Inset shows the configuration of the sample and the experimental set-up. $\mathbf{e}$ and $\mathbf{e}'$ are the unit polarization vectors of the incident and transmitted rays. Conclusion

The non-equilibrium spin polarization in a homogeneous electron gas can drive an electric current due to the SGE as soon as the certain requirement is met, namely the medium belongs to the class of gyrotropic materials. The inverse SGE has also been demonstrated showing that the electric current in non-magnetic but gyrotropic materials results in a steady non-equilibrium spin orientation. It was first observed on a chiral tellurium crystal. The microscopic origin of both direct and inverse SGEs is an inherent asymmetry of electron spin-orbit coupling in gyrotropic systems with removed spin band degeneracy in the k -space. The conversion between the charge current and non-equilibrium spin opens a promising way for the generation, manipulation and detection of spin polarization in spintronic devices. The SGE and its reversal allow one to separate the Dresselhaus and Rashba contributions to the spin-orbit coupling and determine spin relaxation times of resident charge carriers. It also makes it possible to probe the spin-orbit coupling at the Rashba interfaces.

Abstract

Spin-orbit (SO) coupling is the microscopic mechanism that couples the electron's spin degree of freedom to the electron's orbital motion. It emerges from relativistic quantum mechanics described by the Dirac equation. Space and time inversion symmetry enforce characteristic degeneracies in the electronic band structure. A broken space inversion symmetry gives rise to a spin splitting of the bands, the magnitude of which is a measure of the strength of SO coupling. Important SO coupling mechanisms in solids include Rashba and Dresselhaus coupling. SO coupling provides means to address the electrons' spin degree of freedom in solids using, for example, optical orientation and spin precession.

Introduction: Pauli SO coupling

A major justification for the relativistic Dirac equation in quantum mechanics has been its ability to reconcile the apparent contradiction observed in atomic physics, where the interaction of the electron's spin magnetic moment with a magnetic field $\mathbf{B}$ was measured to be twice as large as what one would expect based on the interaction observed for the electron's spin magnetic moment when the electron is orbiting around a nucleus in the electric field due to the steep Coulomb potential V_0 of the atomic core. In the nonrelativistic limit of the Dirac equation, the interaction of the electron spin with a magnetic field is given by the spin Zeeman term (Sakurai, 1967)

$$H_Z = \frac{g}{2} \mu_B \boldsymbol{\sigma} \cdot \mathbf{B}, \quad (1)$$

where $g = 2$ is the g -factor, μ_B is the Bohr magneton, and $\boldsymbol{\sigma} = (\sigma_x, \sigma_y, \sigma_z)$ is the vector of Pauli spin matrices while in the weakly relativistic limit of the Dirac equation [one order beyond Eq. (1)], the interaction of an electron spin that is moving in an electric field is given by the *Pauli spin-orbit (SO) interaction* (Sakurai, 1967)

$$H_{SO} = -\frac{\hbar}{4m^2c^2} (\nabla V_0) \cdot (\boldsymbol{\sigma} \times \mathbf{p}), \quad (2)$$

where $\hbar$ is Planck's constant, m is the mass of the electron, c is the velocity of light, $\mathbf{p}$ is the momentum operator, and V_0 is the potential that gives rise to the electric field seen by the electron. In Eq. (2), V_0 is typically the Coulomb potential of the atomic core. For the angular motion in a central potential $V_0(r)$ that arises for atomic cores, the Pauli SO interaction can be rephrased as an interaction between the electron's orbital angular momentum $\mathbf{L}$ and spin angular momentum $\mathbf{S} = (\hbar/2)\boldsymbol{\sigma}$.

The Dirac Hamiltonian H_D corresponding to the Dirac equation is a 4×4 matrix (Sakurai, 1967)

$$H_D = c \boldsymbol{\alpha} \cdot \mathbf{p} + \beta mc^2 + V_0 \quad (3)$$

where

$$\alpha = \begin{pmatrix} 0 & \boldsymbol{\sigma} \\ \boldsymbol{\sigma} & 0 \end{pmatrix}, \quad (4a)$$

$$\beta = \begin{pmatrix} \mathbb{1}_{2 \times 2} & 0 \\ 0 & -\mathbb{1}_{2 \times 2} \end{pmatrix}. \quad (4b)$$

The eigenfunctions of the Dirac equation are four-component spinors. Their first and second components represent spin up and down in the subspace of positive energies, whereas the third and fourth components represent spin up and down in the subspace of negative energies. The two subspaces are separated by an “energy gap” $2mc^2$. The subspaces are coupled off-diagonally proportional to the momentum $\mathbf{p}$ of the particle. In a nonrelativistic or weakly relativistic limit, the off-diagonal coupling is small. The Schrödinger equation including the spin Zeeman term (1) and Pauli SO coupling (2) is often called *Pauli equation*. It can be derived from the Dirac equation by perturbatively decoupling the “interesting” subspace of positive energies from the “uninteresting” subspace of negative energies (Sakurai, 1967). In lowest order, this yields a term $p^2/(2m)$ representing the nonrelativistic kinetic energy. This term is complemented by the Zeeman term (1). The next order yields Pauli SO coupling (2). If needed, yet higher orders can be derived in a systematic way. However, then it may become advantageous to work directly with the Dirac equation.

It is well known that the Pauli SO coupling (2) affects the energy levels of electrons in atoms. But it also affects the dynamics of electrons in solids, most importantly the band structure $E_n(\mathbf{k})$. The microscopic origin of SO coupling in solids is the steep Coulomb potential of the atomic cores. Therefore, manifestations of Pauli SO coupling (2) generally scale with the atomic number of the constituting atoms in a crystal. Large SO coupling effects generally require constituting atoms from the bottom of the periodic table.

A direct consequence of Pauli SO coupling (2) in the band structure $E_n(\mathbf{k})$ are level splittings that can be parameterized by matrix elements of the SO interaction (2). In effective theories, such matrix elements often provide a convenient parameterization for the effects of SO coupling.

Group theory of SO-coupled systems

Group theory provides a general and rigorous definition for the quantum numbers of a physical system and how these numbers describe physical properties such as matrix elements and selection rules. In the absence of SO coupling, we can discuss separately the symmetry group G of the orbital motion and the symmetry group of the decoupled spin degree of freedom. The latter group is the rotation group $SU(2)$, which reflects the fact that the spin degree of freedom is detached from the orbital motion. The symmetry group of the entire system is then the product group $G \times SU(2)$. It yields separate quantum numbers for the orbital and spin dynamics.

In the presence of SO coupling, the product group $G \times SU(2)$ must be replaced by the double group corresponding to G , and neither the quantum numbers for the orbital motion nor spin are good quantum numbers anymore. In such systems, we get new conserved quantum numbers for the coupled dynamics. In spherically symmetric atoms, the quantum numbers for orbital and spin angular momentum are replaced by total angular momentum. In crystals with band dispersion $E_n(\mathbf{k})$, the band index n becomes a common index for the orbital motion and the spin degree of freedom that classifies the bands according to the irreducible representations of the double group.

For a given wave vector $\mathbf{k}$, we can always find a spin orientation axis $\mathbf{S}(\mathbf{k})$, *local in $\mathbf{k}$ space*, such that we have spin-up and spin-down eigenstates with respect to the axis $\mathbf{S}(\mathbf{k})$. We may indicate the local spin orientation with an additional label $\sigma = \pm$ (unless the branches $E_n(\mathbf{k})$ are anyway spin-degenerate, see below). But we do not call the entire branches $E_{n\sigma}(\mathbf{k})$ with $\sigma = \pm$ spin-up and spin-down, because, in nonmagnetic materials, the direction of $\mathbf{S}$ varies as a function of $\mathbf{k}$ such that, when projecting $\mathbf{S}(\mathbf{k})$ on a fixed direction in spin space and averaging over all occupied states (at thermal equilibrium), the branches contain equal contributions of up and down spinor components. This reflects the fact that, in nonmagnetic materials, we have a vanishing magnetization at $\mathcal{B} = 0$. The pattern of the spin orientation $\mathbf{S}(\mathbf{k})$ as a function of $\mathbf{k}$ defines the *spin texture* that is a distinctive feature of different SO coupling mechanisms for Bloch electrons. Below we discuss examples for $\mathbf{S}(\mathbf{k})$ realized by common SO coupling mechanisms. The spin orientation $\mathbf{S}(\mathbf{k})$ can be attributed to a Zeeman term with a $\mathbf{k}$ -dependent effective magnetic field $\mathcal{B}(\mathbf{k})$, where the magnitude of $\mathcal{B}(\mathbf{k})$ parameterizes magnitude of spin splitting.

An important consequence of symmetries are degeneracies in the energy spectrum of a Hamiltonian that result in constraints for the spin textures $\mathbf{S}(\mathbf{k})$. Here space inversion symmetry (denoted i) and time inversion symmetry (denoted θ , more accurately called reversal of motion) take a special role for the band dynamics of Bloch electrons. The wave vector $\mathbf{k}$ of Bloch electrons is a polar vector (i -odd, that is, i changes $\mathbf{k}$ into $-\mathbf{k}$), and it is also θ -odd. Spin is an axial vector (i -even) while it is θ -odd. Therefore, space inversion symmetry implies that a spinful dispersion is symmetric about $\mathbf{k} = 0$, that is, $E_{n\sigma}(\mathbf{k}) = E_{n\sigma}(-\mathbf{k})$ (even when time inversion symmetry is broken, e.g., by a magnetic field). Time inversion symmetry implies *Kramers degeneracy*, $E_{n\sigma}(\mathbf{k}) = E_{n\bar{\sigma}}(-\mathbf{k})$, where $\bar{\sigma}$ denotes the inverse of a spin orientation σ . Finally, space inversion and time inversion symmetry jointly imply *spin degeneracy* $E_{n\sigma}(\mathbf{k}) = E_{n\bar{\sigma}}(\mathbf{k})$, that is, we have (at least) a twofold degeneracy for every wave vector $\mathbf{k}$ throughout the Brillouin zone (even if i and θ happen to be broken individually). This is summarized in Table 1. If θ is a good symmetry, but a broken space inversion symmetry lifts the spin

Table 1 Band degeneracies due to inversion symmetries.

	$\mathbf{k}$	σ	Degeneracy	
i	$-$	$+$	$E_{n\sigma}(\mathbf{k}) = E_{n\sigma}(-\mathbf{k})$	
θ	$-$	$-$	$E_{n\sigma}(\mathbf{k}) = E_{n\bar{\sigma}}(-\mathbf{k})$	Kramers degeneracy
$i\theta$	$+$	$-$	$E_{n\sigma}(\mathbf{k}) = E_{n\bar{\sigma}}(\mathbf{k})$	Spin degeneracy

degeneracy so that $E_{n\sigma}(\mathbf{k}) \neq E_{n\bar{\sigma}}(\mathbf{k})$, this is often called a $\mathcal{B} = 0$ spin splitting, as it arises in nonmagnetic structures independent of an external magnetic field $\mathcal{B}$. The microscopic mechanism for $\mathcal{B} = 0$ spin splitting is SO coupling.

Band degeneracies enforced by symmetry for SO-coupled bands lay the foundations for more advanced topics exploiting, for example, topology (Chiu et al., 2016).

Mechanisms of SO coupling in solids

In nonmagnetic materials that preserve space and time inversion symmetry, we have an, at least, twofold spin degeneracy of the electronic band structure in the entire Brillouin zone, as discussed in the Section “Group theory of SO-coupled systems.” In these systems, Pauli SO coupling (2) gives rise to gaps in the band structure (Kane, 1966) similar to the familiar SO-induced level splittings in atomic physics.

A broken space inversion symmetry manifests itself as a lifting of the twofold spin degeneracy (Section “Group theory of SO-coupled systems”). This spin splitting can be the consequence of a bulk inversion asymmetry (BIA) of the crystal structure. In confined geometries like quantum wells and heterostructures, a spin splitting may also arise due to a structure inversion asymmetry (SIA) of the confinement potential.

The different SO coupling mechanisms due to BIA can be classified according to the effective magnetic fields $\mathcal{B}(\mathbf{k})$ they give rise to. In general, their functional form follows from the symmetry of the underlying crystal structure. *Rashba SO coupling* (Rashba and Sheka, 1959)

$$H_R = \alpha \cdot (\boldsymbol{\sigma} \times \mathbf{k}) \quad (5)$$

has the same functional dependence on spin $\boldsymbol{\sigma}$ and crystal momentum $\hbar\mathbf{k}$ as Pauli SO coupling (2). It is proportional to a polar vector $\boldsymbol{\alpha}$ that parameterizes the magnitude and orientation of the Rashba effect. Such a vector $\boldsymbol{\alpha}$ is allowed as a bulk property in crystal structures that belong to one of the polar crystal classes that permit a spontaneous electric polarization. Originally, the Rashba effect was first proposed for the polar wurtzite structure (Rashba and Sheka, 1959) that is realized by several III-V and II-VI semiconductors including ZnS, CdSe, GaN, and AlN. The effective magnetic field $\mathcal{B}(\mathbf{k}) = \mathbf{k} \times \boldsymbol{\alpha}$ representing Rashba SO coupling is depicted in Fig. 1A.

Dresselhaus SO coupling (Dresselhaus, 1955)

$$H_{Dr} = \beta [\sigma_x k_x (k_y^2 - k_z^2) + \text{c.p.}], \quad (6)$$

Fig. 1 Effective magnetic field $\mathcal{B}(\mathbf{k})$ due to (A) Rashba SO coupling (5), (B) Dresselhaus SO coupling (7), (C) both Rashba and Dresselhaus SO coupling, and (D) a Dirac-like SO coupling (8). In thermal equilibrium, the resulting spin textures imply a vanishing net magnetization.

where cp denotes cyclic permutation of the preceding term, is realized in bulk zincblende structures including GaAs and InSb. It is cubic in the wave vector $\mathbf{k}$. In quasi-2D quantum wells and heterostructures on a (001) surface, the wave vector component k_z is quantized, so that Dresselhaus SO coupling is linear in the in-plane wave vector $\mathbf{k}_{\parallel} = (k_x, k_y)$

$$H_{\text{Dr}}^{2\text{D}} = \beta \langle k_z^2 \rangle (\sigma_y k_y - \sigma_x k_x). \quad (7)$$

The effective magnetic field $\mathcal{B}(\mathbf{k})$ for Dresselhaus SO coupling (7) is depicted in Fig. 1B.

A *Dirac-like SO coupling*

$$H_{\text{Di}} = \gamma \boldsymbol{\sigma} \cdot \mathbf{k} \quad (8)$$

is realized in chiral crystal structures, that is, structures for which the crystallographic point group contains only proper rotations but no improper rotations as symmetry elements. Examples of chiral structures include α - and β -quartz, and elemental tellurium. The effective magnetic field $\mathcal{B}(\mathbf{k})$ for Dirac-like SO coupling is depicted in Fig. 1D.

Crystal structures of sufficiently low symmetry (e.g., crystal classes C_s , C_2 , and C_1) can support multiple SO coupling mechanisms. In these cases, the effective magnetic field $\mathcal{B}(\mathbf{k})$ is the sum of the fields due to the different SO coupling mechanisms, as illustrated in Fig. 1C.

SIA spin splitting arises due to an asymmetric confinement in engineered quantum structures like quantum wells, at heterostructure interfaces, and at the surface of bulk crystals. It can generally be characterized via a macroscopic external or built-in electric field $\mathcal{E}$ that gives rise to Rashba-type spin splitting as in Eq. (5). This effect can be understood similar to how Pauli SO coupling (2) arises in a weakly relativistic limit from the Dirac equation. This is discussed in more detail in the following Section “SO coupling and band structure of solids.”

The magnitude of SO coupling can be determined experimentally using optical techniques such as optical orientation (Meier and Zakharchenya, 1984; Pikus et al., 1988, see Section “Optical spin orientation”) and electric-dipole spin resonance (Rashba and Sheka, 1991). Theoretical models expand on relativistic band structure calculations (Cardona et al., 1988). Phenomenological models such as $\mathbf{k} \cdot \mathbf{p}$ theory (Kane, 1966) and empirical tight binding (Jancu et al., 1998) may use matrix elements of Pauli SO coupling (2) to parameterize SO coupling effects in the electronic band structure. These matrix elements manifest themselves not only indirectly via the SO couplings (5), (6), or (8), but also directly as energy gaps in the electronic band structure (Kane, 1966).

Electrons exposed to SO coupling H_{SO} experience a spin-dependent correction to their velocity $\mathbf{v}_{\sigma} = \partial H_{\text{SO}} / (\hbar \partial \mathbf{k})$. For Rashba SO coupling, this correction is perpendicular to the vector $\boldsymbol{\alpha}$,

$$\mathbf{v}_{\sigma} = \frac{1}{\hbar} \boldsymbol{\alpha} \times \boldsymbol{\sigma}. \quad (9)$$

Optical spin orientation

Optical selection rules combined with SO coupling provide an efficient scheme called *optical orientation* to generate spin-polarized in nonmagnetic semiconductors (Lampel, 1968; Meier and Zakharchenya, 1984). In direct-gap semiconductors like GaAs, the electron states in the conduction band originate from s -like atomic orbitals (orbital angular momentum $l = 0$), whereas the hole states in the valence band originate from p -like orbitals ($l = 1$). Including spin, the electron states have spin $S = 1/2$, whereas the valence band splits into holes with an effective spin $S = 3/2$ and split-off holes (SH) with $S = 1/2$. The $S = 3/2$ hole states with spin z component $S_z = \pm 3/2$ are denoted heavy-hole (HH) states, whereas the light-hole (LH) states have $S_z = \pm 1/2$. Left (right) circularly polarized photons carry a z component of angular momentum of $-1(+1)$ so that conservation of angular momentum results in the selection rules for optical transitions depicted in Fig. 2. A more detailed analysis of the selection rules shows that the rates T for optical transitions from the HH states to the conduction band are three times larger than the rates for transitions originating from the LH states. In bulk semiconductors, the maximum attainable degree of spin polarization is thus $P = 50\%$, where P is defined as

$$P = \frac{N_+ - N_-}{N_+ + N_-}, \quad (10)$$

and N_+ (N_-) is the number of electrons with spin up (down), respectively. In 2D systems, the degeneracy of the HH and LH states is lifted as sketched in Fig. 2. For resonant excitation at the HH energy, the maximum attainable degree of polarization approaches $P = 100\%$, as confirmed experimentally (Pfalz et al., 2005).

Optical orientation is a direct consequence of the SO gap Δ_{SO} between the HH and LH states with $S = 3/2$ and the SH states with $S = 1/2$. It follows from the transition rates T indicated in Fig. 2 that the spin polarization P becomes zero when $\Delta_{\text{SO}} \rightarrow 0$.

Spin precession and spin relaxation

When the spin $\mathbf{S}$ of an electron with wave vector $\mathbf{k}$ is not aligned with the effective magnetic field $\mathcal{B}(\mathbf{k})$, it can precess similar to how a spin can precess in an external magnetic $\mathcal{B}$. The equation of motion for spin precession reads

Fig. 2 Selection rules and relative transition rates T for optical transitions between valence band (VB) states having an effective spin $S = 3/2$ and $S = 1/2$ and conduction band (CB) states with $S = 1/2$ (Dyakonov and Perel, 1984). The SH states with $S = 1/2$ are separated from the topmost VB with $S = 3/2$ by a gap Δ_{SO} due to SO coupling. In bulk semiconductors the HH states ($S_z = \pm 3/2$) are degenerate with the LH states ($S_z = \pm 1/2$) whereas in quasi-2D systems the LH states (dashed bold lines) are lower in energy than the HH states.

$$\frac{d\mathbf{S}}{dt} = \mathbf{S} \times \mathbf{B}. \quad (11)$$

The precession rate and the direction of the precessional motion are determined by the magnitude and the orientation of the field $\mathbf{B}$.

Random spin precession in the field $\mathbf{B}(\mathbf{k})$ is a common cause for spin relaxation known as *Dyakonov-Perel spin relaxation* (D'yakonov and Perel', 1971). Spin-polarized electrons moving diffusively in a medium with an effective magnetic field $\mathbf{B}(\mathbf{k})$ will undergo momentum scattering events that change the crystal momentum $\hbar\mathbf{k}$ of the electron and thus also the effective magnetic field $\mathbf{B}(\mathbf{k})$ in which the electron's spin precess. Frequent momentum scattering events thus stabilize the spin orientation. This mechanism is similar to motional narrowing in electron spin resonance. A second mechanism contributing to spin relaxation is the *Elliott-Yafet mechanism* that is based on the fact that electron states in the presence of SO coupling (2) are no longer spin eigenstates but a mixture of spin-up and spin-down (Elliott, 1954; Yafet, 1963). A third mechanism is the *Bir-Aronov-Pikus mechanism* that involves electron scattering off holes mediated by electron-hole exchange coupling (Bir et al., 1976). The hyperfine interaction that couples the electron and nuclear spins may also contribute to spin relaxation. Weak antilocalization observed in the magnetoconductivity of quasi-2D systems is a sensitive probe for spin precession and spin relaxation (Knap et al., 1996).

SO coupling and band structure of solids

The energy dispersion of a free Dirac particle ($V_0 = 0$) is shown in Fig. 3A. It consists of two branches representing positive and negative energies for particles and antiparticles and separated by an "energy gap" $2mc^2$. The similarity between Fig. 3A and a simple band structure in solids gives rise to remarkable analogies between relativistic quantum mechanics and the dynamics of Bloch electrons in solids (Blount, 1962; Winkler, 2003).

In the Dirac equation, wave functions are four-component spinors representing spin-up and spin-down in the subspaces of positive and negative energies. The dynamics of Dirac electrons is governed by the off-diagonal coupling between the positive- and negative-energy subspaces proportional to momentum $\mathbf{p}$, see Eq. (3). The envelope-function approximation (Luttinger and Kohn, 1955; Winkler, 2003) provides a qualitatively similar description for the dynamics of Bloch electrons based on an expansion of the electron wave function ψ at finite wave vectors $\mathbf{k}$ in terms of band edge Bloch functions at $\mathbf{k} = 0$. In the resulting effective Hamiltonian for ψ , the subspaces defined by different bands are coupled off-diagonally by terms proportional to crystal momentum $\hbar\mathbf{k}$.

Consider a generic two-band model including the topmost valence band and the lowest conduction band and taking into account the spin of the electrons (Fig. 3B). In the envelope-function approximation, this model is represented by a rescaled version of

Fig. 3 Dispersion of (A) free Dirac particles and antiparticles (B) free Bloch electrons and holes according to a simple two-band model.

the Dirac Hamiltonian (3). More importantly, the perturbative decoupling procedure described in the Section “Introduction: Pauli SO coupling,” that allows one to derive the Pauli equation from the Dirac equation, is likewise applicable to such a two-band model for the dynamics of Bloch electrons. It yields, in lowest order, a kinetic energy term $\hbar^2 k^2 / (2m^*)$, where m^* is the effective mass of the Bloch electrons that describes the curvature of the bands. An external magnetic field $\mathbf{B}$ requires one to replace crystal momentum $\hbar \mathbf{k}$ by kinetic momentum $\hbar \mathbf{k} - e\mathbf{A}$ with $\mathbf{B} = \nabla \times \mathbf{A}$. In this case, the decoupling procedure also yields a Zeeman term $(g^*/2) \mu_B \boldsymbol{\sigma} \cdot \mathbf{B}$ with an effective g -factor g^* . In real materials, the effective quantities m^* and g^* may deviate substantially from the free-electron values predicted by the Dirac equation (Kane, 1966; Roth et al., 1959). Unlike the case of the effective mass m^* , the deviation of the effective g -factor g^* from its free-electron value $g = 2$ is another manifestation of Pauli SO coupling (Roth et al., 1959).

In next order, in the presence of an external or built-in electric field $\mathbf{E}$ representing SIA, the decoupling of the two-band model yields a Rashba SO coupling term that has the same functional form as the Pauli SO coupling (2)

$$H_R = \tilde{\alpha} \mathcal{E} \cdot (\boldsymbol{\sigma} \times \mathbf{p}). \quad (12)$$

The prefactor $\tilde{\alpha}$ is a material parameter that characterizes the crystal structure underlying a specific system. The electric field $\mathcal{E}$ is tunable, for example, via external gates, so that the Rashba SO coupling (12) becomes tunable (Nitta et al., 1997).

It is a common intuitive interpretation of Rashba SO coupling (12) that, in analogy with Pauli SO coupling (2), the crystal electrons are moving with a (Fermi) velocity v in a macroscopic electric field $\mathcal{E}$ that is Lorentz transformed into a magnetic field $\mathbf{B}$ in the electron's rest frame so that the Rashba spin splitting of the moving electron becomes a Zeeman splitting in the electron's rest frame. However, this magnetic field is given by $\mathbf{B} = (v/c^2)\mathcal{E}$ (SI units) and for typical values of $\mathcal{E}$ and v , this relation predicts spin splittings that are orders of magnitude smaller than the experimentally observed values. This discrepancy is due to the fact that the idea of a Lorentz transformation neglects the contribution of the atomic cores to the SO interaction felt by a Bloch electron in a solid. In a microscopic theory, the prefactor $\tilde{\alpha}$ in Eq. (12) is proportional to matrix elements of Pauli SO coupling (2) due to the steep potential V_0 of the atomic cores. Therefore, large atomic numbers Z are generally beneficial for a large Rashba effect. The large- Z requirement generally applies also to other processes exploiting SO coupling in solid-state systems.

Pauli SO coupling (2) is inversely proportional to the gap separating the subspaces of positive and negative energies. Similarly, the Rashba SO coupling in solids is also inversely proportional to the fundamental gap E_g of the material [beyond its dependence on atomic Pauli SO coupling (2)]. However, the former gap has the fixed value $2mc^2$, whereas E_g in solids is amenable for band gap engineering. A smaller gap E_g gives rise to a larger coupling between the bands so that narrow-gap systems generally show a larger Rashba SO coupling.

For electrons in confined geometries such as quantum wells and heterostructure interfaces, the expectation value of an effective or built-in electric field $\mathcal{E}$ vanishes according to Ehrenfest's theorem (on average, there is no force acting on a bound state). Therefore, it was argued that the Rashba effect should be negligible for such bound states (D  rr et al., 1976), in contrast to many experiments confirming a large Rashba effect for such geometries. A more careful inspection of the derivation of the Rashba effect reveals that Rashba SO coupling in the conduction band results from the electric field in the valence band. In quantum-confined structures, the former and latter fields are generally different so that, indeed, Ehrenfest's theorem is not relevant for this scenario (Lassnig, 1985; Winkler, 2003).

In metals the screening length is very short so that the concept of a macroscopic electric field $\mathcal{E}$ giving rise to a Rashba effect (12) breaks down. Nonetheless, experiments find large Rashba spin splittings on metal surfaces such as the gold (111) surface (LaShell et al., 1996). This spin splitting has also been confirmed by atomistic ab initio calculations (Bihlmayer et al., 2006). A simple tight-binding model for the Rashba spin splitting on metal surfaces was proposed by Petersen and Hedeg  rd (2000).

Conclusion

SO coupling in solids is a relativistic effect that emerges from the Dirac equation. Specific mechanisms include Rashba and Dresselhaus SO coupling. Its functional form is a consequence of crystal symmetry. The microscopic origin of SO coupling experienced by Bloch electrons is the steep Coulomb potential of the atomic cores so that constituting atoms with large atomic numbers are generally beneficial in the quest for systems with large SO couplings.

The fundamental physics of SO coupling in solids lays the foundation for advanced topics including the spin Hall effect, the spin galvanic effect, SO interaction-based spintronics, and spin torques discussed elsewhere in this volume.

Abstract

Spin-orbit interaction (SOI) is a relativistic effect and produces a momentum dependent effective magnetic field when electron spins travel in an electric field. The spin angular momentum and orbital motion of electrons are coupled by SOI, e.g., leading to the spin Hall effect, where spin-up and -down electrons are deflected into opposite directions. By exploiting these unique features, we can create spin functionalities in SOI systems without using an external magnetic field. SOI based spintronics is often called "spin-orbitronics". This chapter focuses on Rashba and Dresselhaus SOIs and their applications for spintronics in semiconductor heterostructures. Especially Rashba SOI is rather interesting since the strength is controlled by the gate voltage on top of the semiconductor's two-dimensional electron and hole gases. By utilizing the effective magnetic field induced by the Rashba SOI, spin generation, manipulation, and detection are possible by electrostatic ways. However, the drawback of SOI is to give rise to spin relaxation because of the momentum dependent magnetic field. Long spin coherence is achieved by special spin helix state where both Rashba and Dresselhaus SOIs are equal.

Key points

- Spin-orbit interaction (SOI) is a relativistic effect and produces a momentum dependent effective magnetic field when electron spins travel in an electric field.
- Spin angular momentum and orbital motion of electrons are coupled by SOI, e.g., leading to spin Hall effect, where spin-up and -down electrons are deflected into opposite directions.
- By exploiting these unique features, we can create spin functionalities in SOI systems without using an external magnetic field.
- Rashba SOI is important since its strength is controlled by a gate voltage on top of semiconductor's two-dimensional electron and hole gases.
- By utilizing effective magnetic field induced by Rashba SOI, spin generation, manipulation, and detection are possible by electrostatic ways.
- However, drawback of SOI is to give rise to spin relaxation because of momentum dependent magnetic field.
- Long spin coherence is achieved by persistent spin helix state where both Rashba and Dresselhaus SOIs are equal.
- SOI-based electron spin resonance (ESR) techniques are developed by using ac-electric fields for spin manipulations.

Spin-orbit interaction (SOI) is a relativistic effect and produces a momentum dependent effective magnetic field when electron spins travel in an electric field. Long spin coherence is achieved by special spin helix state where both Rashba and Dresselhaus SOIs are equal.

Introduction

Spin degeneracy in electronic bands is lifted by spin-orbit interaction (SOI) in crystals without inversion symmetry. The bulk SOI effects are established in both noncentrosymmetric zinc-blende and wurtzite semiconductors by Dresselhaus (1955) and Rashba (1960), respectively. Bychkov and Rashba extended the concept of SOI to two-dimensional electron gases (2DEG) with structure inversion asymmetry (SIA) (Bychkov and Rashba, 1984). These SOIs play important roles for many interesting spin-related phenomena in solid state physics (Manchon et al., 2015). The essence of SOI is that the moving electrons in an electric field feel an effective magnetic field even without any external magnetic field. The internal electric field of the Dresselhaus SOI originates from the microscopic Coulomb potential gradient of the atomic core region, the strength of which is generally difficult to modulate. The bulk Dresselhaus SOI coefficient γ is considered to be a material-constant parameter. It should be noted that the spin splitting energy due to the Dresselhaus SOI can be modulated by carrier density since the SOI is affected by electron velocity. On the contrary, the internal electric field of the Rashba SOI originates from both the *microscopic* Coulomb potential induced by the atomic core and the *macroscopic* potential gradient caused by hetero-interface and quantum well (QW) in semiconductor heterostructures (Winkler, 2003). Although the microscopic electric field is a material-constant parameter, as is the Dresselhaus SOI, the macroscopic electric field can be modulated by applying an external gate bias voltage of 2DEG. This enables us to electrically control Rashba SOI coefficient α (Nitta et al., 1997; Engels et al., 1997). The strength of SOI depends on both electric fields and electron momentum. It should be emphasized that the SOI effects in solids are much enhanced in contrast to that in vacuum. This is because the electric field near the atomic core is huge and the electron wave function varies rapidly in space, resulting in huge momentum.

By exploiting these unique features, we can create spin functionalities in SOI systems without using an external magnetic field. The SOI-based spintronics is often called "spin-orbitronics." The electrostatic control of spin degree of freedom can be used for generation, manipulation, and detection of spins, which are important techniques for spintronics and quantum information. This chapter focuses on Rashba and Dresselhaus SOIs and their applications in semiconductor heterostructures. However, the drawback of SOI is to give rise to spin relaxation because of the momentum dependent magnetic field. Long spin coherence is achieved by special spin helix state where both Rashba and Dresselhaus SOIs are equal.

Origin of spin-orbit interaction in semiconductors

The SOI in vacuum is described by the Thomas term in the Pauli equation,

$$H_{SO} = -\frac{1}{2m_0c^2} \mu_B \sigma \cdot (\vec{p} \times \nabla V_0) = -\mu_B \sigma \cdot \left(\frac{\vec{p} \times \vec{E}}{2m_0c^2} \right) \quad (1)$$

Here m_0 , c , μ_B , σ and V_0 are the free electron mass, the light velocity, the Bohr magneton, the Pauli spin matrix, and the scalar potential, respectively. The electron momentum is given by $\vec{p} = \hbar \vec{k}$ with Planck constant $\hbar$ and wavenumber $\vec{k}$. In analogy to the Zeeman Hamiltonian, $H_Z = -\mu_B \sigma \cdot \vec{B}$, the effective magnetic field $\vec{B}_{eff}$ of SOI is given by

$$\vec{B}_{eff} = \frac{\vec{p} \times \vec{E}}{2m_0c^2} \quad (2)$$

It is clear that the effective magnetic field $\vec{B}_{eff}$ is induced perpendicular to both the electron momentum $\vec{p}$ and the electric field $\vec{E}$. In the relativistic quantum theory, $2m_0c^2$ is the energy gap between an electron and a positron, which is a negative energy particle with the negative mass predicted by Dirac. The energy scale of $2m_0c^2$ is ~ 1 MeV; thus, SOI effects are negligible for a particle with non-relativistic momentum in vacuum. On the other hand, in crystalline solids, the energy-band gap is reduced to ~ 1 eV in typical semiconductors. Since the Dirac gap is replaced by the energy-band gap according to the $k \cdot p$ perturbation theory (Winkler, 2003), it results in huge enhancement of the SOI in semiconductors.

The electron wave function in semiconductors is characterized by both a Bloch function and an envelope function. In the Bloch part, the electron wave is rapidly modulated by the atomic core potential, while the electron wave in the envelope part is gradually modulated by the periodic crystalline structure. The origin of the enhancement of the SOI in semiconductors is due to the Bloch part, where both the electron momentum and the electric field are enlarged by the fast oscillation of the electron wave and the strong confinement near the atomic core, respectively (Winkler, 2003).

In noncentrosymmetric zinc-blende semiconductors such as GaAs or InSb, the electric field due to the ionized atoms in the crystal can be an origin of SOI in Eq. (1). This is the so called Dresselhaus SOI. The derivation of Dresselhaus SOI is obtained from the $k \cdot p$ perturbation theory based on 14×14 matrix Hamiltonian for the extended Kane model. The bulk Dresselhaus SOI is given by the following equation.

$$H_D^{bulk} = \gamma \left[\sigma_x k_x (k_y^2 - k_z^2) + \sigma_y k_y (k_z^2 - k_x^2) + \sigma_z k_z (k_x^2 - k_y^2) \right] \quad (3)$$

Here, γ is bulk Dresselhaus SOI coefficient which is a material constant, $\sigma_x, \sigma_y, \sigma_z$ are the Pauli spin matrix and, k_x, k_y, k_z are electron wavenumber. In a zinc-blende semiconductor 2DEG QW grown along [001] direction such as GaAs and InAs, the linear Dresselhaus SOI is expressed by

$$H_{D1} = \beta_1 (k_x \sigma_x - k_y \sigma_y) \quad (4)$$

Here, we use $k_z = 0$ and $k_z^2 \rightarrow \langle k_z^2 \rangle$ for a [001] QW, and introduce a linear Dresselhaus coefficient $\beta_1 = -\gamma \langle k_z^2 \rangle$. When the QW confinement wavenumber $k_z^2 \sim (\pi/d_{QW})^2$ with the QW thickness d_{QW} is much larger than the Fermi wavenumber k_F , the Dresselhaus k -cubic term is negligible. Although the bulk Dresselhaus SOI γ is not controllable, the linear Dresselhaus SOI β_1 can be tuned by the QW thickness d_{QW} .

In addition to the Dresselhaus SOI in zinc-blende semiconductors, the spin degeneracy is lifted due to the SIA of the confining potential of 2DEG QW. When the confinement potential of QW is symmetric, the Rashba SOI caused by macroscopic electric field in the QW is zero. By applying an external gate bias on top of 2DEG, the potential profile can be modulated, and the asymmetric QW potential causes a finite Rashba SOI strength that lifts the spin degeneracy. The advantage of the Rashba SOI is that the strength of SOI can be controlled by the gate voltage (Nitta et al., 1997; Engels et al., 1997; Schäpers et al., 1998). The electric field direction is perpendicular to the 2DEG hetero-structure. By considering the z -component electric field in Eq. (1), the form of Rashba SOI is expressed by

$$H_R = \frac{\alpha}{\hbar} (\vec{z} \times \vec{p}) \cdot \vec{\sigma} = \alpha (k_x \sigma_y - k_y \sigma_x) \quad (5)$$

where α is the Rashba SOI coefficient, which depends on the band parameters and the electric field in the QW.

According to the $k \cdot p$ perturbation theory (Winkler, 2003), the Rashba SOI coefficient α is given by the following equation

$$\alpha = \frac{\hbar^2 E_P}{6m_0} \left\langle \Psi(z) \left| \frac{d}{dz} \left(\frac{1}{E_F - E_{\Gamma_7}(z)} - \frac{1}{E_F - E_{\Gamma_8}(z)} \right) \right| \Psi(z) \right\rangle \quad (6)$$

where $\Psi(z)$ is the envelope wave function for the confined electron, E_P is the inter-band matrix element, E_F is the Fermi energy in the conduction band, and $E_{\Gamma_7}(z)$ and $E_{\Gamma_8}(z)$ are positions of the band edge energies for Γ_7 (spin split off band) and Γ_8 (the highest valence band) bands, respectively. Contribution to Eq. (6) can be split into two parts: (i) the field part, which is related the electric field in the QW and (ii) interface part, which is related to band discontinuities at the heterointerface (Schäpers et al., 1998).

For many years, there has been an intense discussion about the Rashba SOI. It had been considered that the Rashba SOI should be very small because the average electric field for the bound state in QWs should be zero, i.e., $\langle E \rangle = 0$ in order to satisfy the condition that there is no force acting on an electron bound state. In fact, this controversy is resolved by Eq. (6). It is clear that the Rashba spin splitting in conduction band originates from the electric field in the valence band.

Both Dresselhaus and Rashba SOIs induce spin split subbands in energy dispersion relation and spin-orbit (SO) effective magnetic field B_{eff} . The SO fields at the Fermi surface are illustrated in Fig. 1 for the case of (a) Rashba SOI and (b) linear Dresselhaus SOI. The arrow directions also correspond to the SO induced effective field. These momentum dependent SO fields are an origin of spin relaxation. It is important to note that the spin relaxation is suppressed when both are present with equal magnitude. As is shown in Fig. 1(c), the total SO fields are unidirectional along [110] directions, resulting in the so-called persistent spin helix state (PSH) (Schliemann et al., 2003; Bernevig et al., 2006a). We will discuss it in the following section "Spin relaxation and its suppression for long spin coherence."

Gate controlled Rashba SOI

The spin field effect transistor (spin-FET) (Datta and Das, 1990) was proposed with two assumptions (i) the gate controlled Rashba SOI and (ii) spin injection and detection using ferromagnetic contacts. The schematic spin-FET structure is illustrated in Fig. 2. The injected spin direction from the ferromagnetic contact should be perpendicular to the Rashba SOI field for effective spin precession

Fig. 1 Spin-orbit induced effective magnetic fields at Fermi energy. (a) Rashba SOI, (b) Dresselhaus SOI, (c) Persistent spin Helix state ($\alpha = \beta_1$). control. Fundamental obstacle for spin injection from a ferromagnetic electrode to a semiconductor channel is pointed out because of conductivity mismatch (Schmidt et al., 2000). The momentum difference between spin up and down at the Fermi energy is described by $k_{F\uparrow} - k_{F\downarrow} = 2\alpha m^*/\hbar^2$, where m^* is an effective mass of electron. The spin precession angle φ is given by

$$\varphi = \frac{2\alpha m^*}{\hbar^2} L \quad (7)$$

when an electron spin travels in a channel length L of the spin-FET. It should be emphasized that spin precession angle φ does not depend on k_F and spin splitting energy $\Delta_R = 2\alpha k_F$, so that all the modes in a narrow channel can provide the same precession angle. This unique feature is important to make spintronics devices. The gate control of Rashba SOI parameter α itself instead of Δ_R is crucial to realize spintronics devices.

One of the ways to obtain the Rashba SOI parameter α is to measure the beating pattern in the Shubnikov de-Haas (SdH) oscillations (Nitta et al., 1997; Engels et al., 1997; Schäpers et al., 1998). The origin of the beating in the SdH oscillations comes from the spin-split two subband at the Fermi energy. Note that one should be careful about the origin of the beating when we have a second subband in a QW since the magneto inter-subband scattering (MIS) also makes a beating pattern in the SdH oscillations (Rowe et al., 2001).

In InGaAs-based 2DEGs, Rashba SOI strength is larger than that of Dresselhaus SOI. An InGaAs/InAlAs heterostructure used to evaluate the Rashba SOI is shown in Fig. 3(a) (Nitta et al., 1997). A Si-doped InAlAs carrier supplied layer is placed underneath an InGaAs 2DEG channel to make asymmetric QW potential profile as shown in Fig. 3(b). By application of negative gate voltage V_g , the potential profile in the QW becomes more asymmetric, leading to a reduction of $k_F = \sqrt{2\pi N_s}$ and an enhancement of α . Here, k_F is the Fermi momentum and N_s is the carrier density of the 2DEG. Beating patterns appeared in SdH oscillations are shown in Fig. 4(a), which are analyzed to evaluate α . As is expected, the obtained α is enhanced by negative voltage V_g (by reducing N_s as shown in Fig. 4(b)).

An alternative way to evaluate SOI parameter is to perform weak anti-localization (WAL) analysis. This is because the spin splitting energy Δ_R can be related to spin relaxation time τ_s if the spin relaxation is governed by the D'yakonov-Perel (DP) mechanism as is discussed in Chapter 3. It has been demonstrated that the Rashba SOI can be controlled by the design of asymmetry in QWs from the WAL analysis (Koga et al., 2002; Lin et al., 2005). Optical measurements are useful to evaluate both Rashba and Dresselhaus SOI parameters (Meier et al., 2007), however, they are not easy to apply gate-fitted samples.

The SdH oscillation and WAL analyses are not always accurate to evaluate the SOI parameter when the Rashba and Dresselhaus SOI strengths are close to each other. Recently, the theoretical model for WAL in the vicinity of PSH state was developed and Rashba and Dresselhaus SOI strengths were experimentally obtained in a GaAs/AlGaAs heterostructure (Weigelt et al., 2020). A novel concept to determine the Rashba and Dresselhaus SOI ratio without any fittings was proposed (Scheid et al., 2008) and experimentally demonstrated in InGaAs wires by utilizing in-plane Zeeman field (Sasaki et al., 2014). By using this method, the gate-controlled persistent spin helix (PSH) was confirmed.

Spin relaxation and its suppression for long spin coherence

Spins of electrons in solids are not conserved quantity in contrast to charges of electrons. The information of spins is lost and leads to the so-called spin relaxation by several reasons. In the epitaxially grown III-V compound QWs with the Rashba and Dresselhaus SOIs, the D'yakonov-Perel (DP) mechanism is generally dominant for spin relaxation (Dyakonov and Perel, 1971). The Rashba SOI causes an effective magnetic field B_{eff} which is pointing perpendicular to the momentum direction in the 2DEG plane. The spin of electrons is precessing around the effective field. In a diffusive 2DEG, the momentum direction of electron changes frequently, and hence so does the direction of B_{eff} . Due to the random change in B_{eff} , the spin orientation is randomized and the spin loses the memory of its initial spin direction. The DP spin relaxation is caused not only by the Rashba SOI but also by the Dresselhaus SOI. Generally speaking, the DP spin relaxation is expected if the system has momentum dependent effective field B_{eff} due to SOI spin splitting energy Δ_R .

From the above DP spin relaxation picture, we can estimate the spin relaxation time. The spin is initially precessing around a certain effective magnetic field direction with a typical frequency of $\omega = \Delta_R/\hbar$ and during a typical scattering time τ . After a scattering event, the direction of B_{eff} is randomly changed, and the spin starts to precess around the new B_{eff} direction. Hence, after a certain number of scattering events there is no correlation anymore between the initial and final spin states. The precise time scale on which the spin loses its memory depends on the typical spin precession angle between scattering events $\delta\phi = \omega\tau = \Delta_R\tau/\hbar$. For $\delta\phi \ll 1$, the precession angle is small between succeeding scattering events, so that the spin vector experiences a slow angle diffusion. During a time interval t , the number of random steps is t/τ . For uncorrelated steps in the precession angle we have to sum the squared precession angles $\delta\phi^2 = (\Delta_R\tau/\hbar)^2$, and the total squared precession angle after time t is $(\Delta_R\tau/\hbar)^2 t/\tau$. The spin relaxation time τ_s can be defined as the time at which the total precession angle becomes of the order of unity. Hence the spin relaxation time is given by $\tau_s \approx \hbar^2/(\Delta_R^2\tau)$. The spin relaxation time τ_s can be derived from WAL analysis, which can be related to spin splitting energy $\Delta_R = 2\alpha k_F$ (therefore α).

It is very crucial to suppress the spin relaxation while keeping the strength and the controllability of SOI. One of the ways to suppress spin relaxation is to confine electrons to one-dimensional narrow wire structures whose width is of same scale of spin precession length $L_{so} = \hbar^2/\alpha m^*$ due to the Rashba SOI. This suppression of spin relaxation due to lateral confinement effect have been theoretically investigated (Mal'shukov and Chao, 2000; Kettemann, 2007) and have been experimentally demonstrated with optical way (Holleitner et al., 2006) and WAL analysis (Schäpers et al., 2006; Kunihashi et al., 2009).

Most effective way to suppress the DP spin relaxation is to utilize the so-call persistent spin helix (PSH) condition (Schliemann et al., 2003; Bernevig et al., 2006a,b), where Rashba SOI strength α is equal to linear Dresselhaus SOI β_1 . Schematic images of spin relaxation and PSH are shown in Fig. 5(a) and (b), respectively. In the PSH condition ($\alpha = \beta_1$), conservation of spin polarization is preserved even after scattering events. This conservation is predicted to be robust against all forms of spin-independent scattering, including electron-electron interaction, but is broken by spin-dependent scattering and a cubic Dresselhaus term. The PSH in semiconductor QWs was confirmed by optical transient spin-grating spectroscopy by Koralek et al. (2009). They found enhancement of spin life time by two orders magnitude near the exact PSH point.

Under the PSH state ($\alpha = \beta_1$), the effective magnetic field is unidirectional as is shown in Fig. 1(c), resulting in coherent spin propagation with helical spin texture. This helical spin texture pattern has been observed by optical measurements (Walser et al., 2012; Ishihara et al., 2014). Furthermore, it has been demonstrated that the helical spin coherence is enhanced by introducing drift

Fig. 5 Schematic images for (a) spin relaxation and (b) persistent spin helix state. J. D. Koralek, C. P. Weber, J. Orenstein, B. A. Bernevig, Shou-Cheng Zhang, S. Mack & D. D. Awschalom (2009) Emergence of the persistent spin helix in semiconductor quantum wells. *Nature* 458: 610–613.

motion of spins by in-plane electric field (Kumihashi et al., 2016). The gate-controlled PSH state (Kohda et al., 2012a) and gate-controlled switching between PSH and inverse PSH ($-\alpha = \beta_1$) (Yoshizumi et al., 2016) have been confirmed by transport measurement. These experimental demonstrations are breakthroughs toward minimizing and controlling spin relaxation. Spin complementary field effect transistor design is proposed on the basis of gate-tunable spin helix states (Kumihashi et al., 2012).

Spin generation and detection using SOI

SOI can generate spin current and spin accumulation due to the spin and momentum coupling nature. Charge currents are converted to transverse spin currents by the spin Hall effect as shown in Fig. 6(a). The spin polarization direction is out-of-plane. SOI induced effective field B_{eff} gives rise to the Edelstein-Rashba effect (spin accumulation) as shown in Fig. 6(b). In this case, the spin polarization direction is parallel to B_{eff} , namely in-plane. In contrast to metal systems, a band structure affected by the SOI in semiconductor systems lead to an intrinsic spin Hall effect even in the absence of scattering events. The intrinsic spin Hall effect in valence-band holes was first predicted by Murakami et al. (2003). A universal intrinsic spin Hall effect in a ballistic Rashba 2DEG system was calculated by Sinova et al. (2004). The universal spin Hall conductivity is given by $e/8\pi$. It is important to note that the spin Hall conductivity vanishes in a diffusive Rashba 2DEG system (Inoue et al., 2004). The spin Hall effect in heavy-holes in confined QW was studied by Schieman and Loss (2005). In contrast to the Rashba 2DEG systems, the intrinsic spin Hall effect in a hole system does not vanish even in a diffusive case. Quantized spin Hall conductance has been theoretically predicted (Bernevig et al., 2006a,b) and experimentally demonstrated in HgTe/CdTe QWs (Koenig et al., 2007).

Intuitive picture of the spin Hall effect in the Rashba 2DEG systems is provided by the spin transverse force (Li et al., 2005). Using the Heisenberg equation of motion and the commutation relation of the Pauli spin matrix, the second derivative of the position operator gives the following spin transverse force on a moving electron (Li et al., 2005).

Fig. 6 Schematic illustrations for (a) spin Hall effect and (b) Rashba-Edelstein effect. G. Bauer (2004) Mesmerizing semiconductors. *Science* 306: 1898.

$$\vec{F} = -\frac{2m^*\alpha^2\sigma_z}{\hbar^3}\vec{p} \times \hat{z} \quad (8)$$

This spin transverse force tends to form a σ_z spin current perpendicular to the momentum direction $\vec{p}$. When the charge currents are flowing toward x-direction with momentum p_x , σ_z spin currents are generated along y-directions because of the spin transverse force.

Experimental observation of the spin Hall effect in bulk GaAs and strained InGaAs was demonstrated with the use of Kerr rotation microscopy. Without applying any external magnetic field, the out-of-plane spin polarized carriers with opposite sign were detected at the two edges of the sample. The amplitude of the spin polarization was so weak, and the mechanism was originated by the extrinsic spin Hall effect such as the skew scattering (Engel et al., 2005). The spin Hall effect in a GaAs 2D hole system was observed by Wunderlich et al. (2005). The out-of-plane spin polarized carriers were detected by light emitting diodes, and sign of the spin polarization was switched by the electric field direction. The authors claimed that the intrinsic spin Hall effect is responsible for their system.

SOI induced effective field B_{eff} gives rise to the spin-momentum locking effects; the Edelstein-Rashba effect (inverse spin galvanic effect) and the spin galvanic effect. These two effects are also useful to generate and to detect spin polarized carrier in non-magnetic materials. Because of the Hamilton's equation $\vec{v} = \partial H_R / \partial \vec{p}$, the spin galvanic effect is given by $\vec{j}_c = -e\alpha(\vec{z} \times \vec{S})/\hbar$, where $\vec{S}$ is the non-equilibrium spin density created by either electrically and optically and $\vec{j}_c$ is the induced charge density (Wunderlich et al., 2009). This concept was originally developed in the context of optical manipulation of spin in semiconductors (Ivchenko and Pikus, 1978) and observed in quantum wells (Ganichev, 2008). The Onsager reciprocal of spin galvanic effect, the inverse spin galvanic effect (sometimes called the Edelstein-Rashba effect (Edelstein, 1990)) has been observed in strained semiconductor InGaAs (Kato et al., 2004a,b) and QWs (Ganichev et al., 2006). Following the Rashba symmetry the spin density generated by the current is $\vec{S} = \alpha m^* (\vec{z} \times \vec{j}_c) / e\hbar$. The spin Hall effect and the Edelstein-Rashba effect are of particular significance in ferromagnet/heavy metal bilayer systems for manipulating the magnetization of ferromagnets electrically.

An electrical detection of the spin Hall effect is difficult since the same amounts of charges are accumulated in the Hall probes. However, the inverse spin Hall effect can be used for the electrical detection of spin polarized carriers. Spin currents are converted to transverse charge currents by the inverse spin Hall effect, and the accumulated charge can be detected by the Hall probe. Wunderlich et al. (2010) have combined the concept of the spin Hall effect with the spin FET, and have successfully demonstrated the so-called spin Hall transistor operation. Spin polarized carriers are generated by circularly polarized optical light, and then the direction of spins is controlled by the gate voltage through the Rashba SOI in a GaAs 2DEG channel, and finally the modulated spins are electrically detected by the inverse spin Hall effect.

The experimentally observed spin polarization due to the spin Hall effect and the Edelstein-Rashba effect is very tiny (much less than 1%) in semiconductor channels. So the Stern-Gerlach spin filter has been proposed (Fig. 7) by using the spatial gradient of the Rashba SOI (Ohe et al., 2005). A spatial gradient of the effective magnetic field due to the Rashba SOI causes spatial spin separation similar to the Stern-Gerlach effect. Almost 100% spin polarization can be realized even without applying any external magnetic fields and without attaching ferromagnetic contacts. In this case, the spin polarized orientation is not out-of-plane σ_z but in-plane

Fig. 7 Stern-Gerlach spin filter operation based on Rashba SOI. Yellow region indicates spatial gradient of Rashba SOI, resulting in spatial gradient of effective magnetic field. J Ohe, M Yamamoto, T Ohtsuki, J Nitta(2005) Mesoscopic Stern-Gerlach spin filter by nonuniform spin-orbit interaction. *Physical Review B* 72: 041308 R.

σ_y . The spin polarization persists even in the presence of randomness. This Stern-Gerlach spin filter based on inhomogeneous Rashba SOI was demonstrated in semiconductor quantum point contacts (Kohda et al., 2012a,b). In this experiment, the spin polarization of 70% was confirmed by shot noise measurements. Such a spin-filter device can be also used for electrical spin detection (Kohda et al., 2019).

Topological insulators have an insulating gap in the bulk, but have topologically protected edge states due to the time reversal symmetry. This type of insulator is realized by an inversion between conduction and valence bands due to strong SOI and the edge states have a distinct helical property: two states with opposite spin-polarization counterpropagate at a given edge; for this reason, they are also called helical edge states. In two dimensions the helical edge states give rise to the quantum spin Hall (QSH) effect, in the absence of any external magnetic field. A theoretical prediction of the QSH has been proposed and experimentally demonstrated in HgTe/CdTe semiconductor QWs (Bernevig et al., 2006a,b; Koenig et al., 2007). By varying the thickness of the QW, the band structure changes from a normal to an “inverted” type at a critical thickness d_c . For thin QWs with well width $d_{QW} < 6.3$ nm, the insulating regime shows the conventional behavior of vanishingly small conductance at low temperature. However, for thicker QWs ($d_{QW} > 6.3$ nm), the nominally insulating regime shows a plateau of residual conductance close to $2e^2/h$. The residual conductance is independent of the sample width, indicating that it is caused by edge states. Furthermore, the residual conductance is destroyed by a small external magnetic field.

Spin manipulation by Aharonov-Casher spin interference

An electron acquires a phase around magnetic flux due to the vector potential leading to the Aharonov-Bohm (AB) effect in an interference loop (Aharonov and Bohm, 1959; Tonomura et al., 1986). From the view point of inherent symmetries between magnetic field and electric field in the Maxwell equations, Aharonov and Casher have predicted that a magnetic moment acquires a phase around a charge flux line (Aharonov and Casher, 1984). It is pointed out that the AC phase shift can be derived from SOI (Balatsky and Al'tshuler, 1993). A. G. Aronov and Y. B. Lyanda-Geller have derived a spin-orbit Berry phase in conducting rings with SOI (Aronov and Lyanda-Geller, 1993). T. Qian and Z. Su have obtained the AC phase, which is the sum of spin-orbit Berry phase and spin dynamical phase in a one-dimensional ring with SOI (Qian and Su, 1994).

Mathur and Stone have theoretically shown (Mathur and Stone, 1992) that the effects of SOI in disordered conductors are manifestations of the AC effect in the same sense as the effects of weak magnetic fields are manifestations of AB effect. They have proposed the electronic AC effect in a mesoscopic interference loop made of GaAs 2DEG with the Dresselhaus SOI. The AC spin interference based on this proposal was not reported since the Dresselhaus SOI strength is not controlled by an electrostatic way.

Electrostatic manipulation of spins is of crucial for spintronics. An AC spin-interference device has been proposed on the basis of the gate controlled Rashba SOI (Nitta et al., 1999; Meijer et al., 2002). The schematic structure of the spin interference device is shown in Fig. 8. The spin interference can be expected in a ring-shaped loop with the Rashba SOI because the spins of electrons precess in opposite directions between clockwise and counter clockwise traveling directions in the ring. The relative difference in spin precession angle at the interference point causes the phase difference in the spin wave functions. The gate electrode, which covers the whole area of the ring, controls the Rashba SOI, and therefore, the interference. The advantage of this proposed spin-interference device is that conductance modulation is not washed out even in the presence of multiple modes since the spin precession angle does not depend on the wavenumber as shown in Eq. (5). Furthermore, this Rashba spin interferometer works without ferromagnetic electrodes in contrast to spin-FET.

The conductance of a one-dimensional ring with the Rashba SOI α and its radius r when electrons travel *halfway around the ring* is given by Nitta et al. (1999), Frustaglia and Richter (2004), Wang and Vasilopoulos (2005)

$$G_R = \frac{e^2}{h} \left[1 - \cos \left\{ \pi \sqrt{1 + \left(\frac{2m^* \alpha r}{\hbar^2} \right)^2} \right\} \right] = \frac{e^2}{h} \left[1 - \cos \left\{ \frac{2\pi r m^* \alpha}{\hbar^2} \sin \theta - \pi(1 - \cos \theta) \right\} \right] \quad (9)$$

The acquired AC spin phase can be written as the sum of two phases; $2\pi r m^* \alpha / \hbar^2$ and $\pi(1 - \cos \theta)$, as is shown in the last expression in Eq. (9). Here, θ is defined by $\tan \theta = 2m^* \alpha r / \hbar^2$, and corresponds to the effective magnetic field direction in the rotational frame of

Fig. 8 Schematic illustration of spin interference device based on Rashba SOI. J. Nitta, F. Meijer, H. Takayanagi (1999) Spin-interference device. *Applied Physics Letters* 75: 695.

reference. The former term is sometimes called the dynamical part of the AC spin phase, because of its dependence on the distance traveled by the electrons and its relation to spin precession angle. The latter term is a geometrical phase since it only depends on the solid angle θ , and not on spatial parameters. Such geometric phases were discovered by Berry from the basic laws of quantum mechanics (Berry, 1984), and received considerable attention. Berry shows that the wavefunction obtains a non-trivial phase when a parameter in the Hamiltonian is changed in a cyclic and adiabatic way.

The conductance of a mesoscopic ring is affected by several quantum interference effects. The well-known AB effect results in a resistance oscillation with a magnetic flux period of h/e . The AB effect is sample specific and very sensitive to the Fermi wave length, therefore, the interference pattern is rapidly changed by the gate voltage. Complex gate voltage dependence has been reported in an AC experiment in a single ring fabricated from HgTe/HgCdTe QWs (König et al., 2006). Therefore, a detailed analysis is necessary to compare with the AC theory. In order to detect the AC effect clearly, it is better to focus another quantum interference phenomenon, the Al'tshuler-Aronov-Spivak (AAS) effect (Al'tshuler et al., 1981). The AAS effect is the AB effect of *time reversal symmetric* paths, where the two wave function parts go all around back to the origin on identical paths, but in opposite directions. If there is magnetic flux inside the paths the resistance will oscillate with the period of $h/2e$. In this time reversal symmetric paths, any other phases which are acquired by path geometry and/or the Fermi wave length (carrier density) differences will be identical and will be canceled out. However, the time reversal AAS effect depends on the spin phase modulated by the Rashba SOI. The time reversal symmetric AC spin interference can be picked up by using an array of rings instead of a single ring.

The experiments to detect the AC spin interference have been performed by using gate fitted 40×40 rings array made of an InAlAs/InGaAs 2DEG as shown in inset of Fig. 9. Magnetoresistance curves were measured for various gate voltages to tune the Rashba SOI strengths. The AAS oscillations at the gate voltage of -2.4 V are shown in Fig. 9(a). 2D plot for the gate voltage dependence of AAS oscillations is displayed in Fig. 9(b). At zero magnetic field, a phase contribution from the orbital part of the wave-function is canceled out in the time-reversal paths, therefore, the spin part of the wave-function controls the AAS amplitude through the Rashba SOI modulation by V_g . Fig. 9(c) shows the AAS amplitude plotted against the gate voltage at zero magnetic field. The result shown in Fig. 9(c) is consistent with gate voltage dependence of the Rashba SOI parameters obtained by analysis of SdH oscillations using the same InAlAs/InGaAs 2DEG. Therefore, the AAS amplitude modulation is ascribed to the spin interference in the time-reversal paths, i.e., the time-reversal AC effect (Bergsten et al., 2006; Nagasawa et al., 2012).

A geometric phase of the most fundamental spin-1/2 system, the electron spin, had not been observed directly and controlled independently from dynamical phases. The geometrical phase shift and its topological transition by in-plane Zeeman field was theoretically investigated in the AC spin interference device (Saarikoski et al., 2015). Control of the geometric phase appeared in Eq. (9) was demonstrated by gate voltage (Nagasawa et al., 2012) and Zeeman in-plane field (Nagasawa et al., 2013). It was also shown that the Aharonov-Casher oscillations in various radius arrays collapse onto a universal curve if the radius and the strength of Rashba SOI are taken into account. The result is interpreted as the observation of the effective spin dependent flux through a ring.

Spin manipulations by SOI-based ESR

Electron spin resonance (ESR) is of importance for the manipulation of individual electron spins in quantum information technologies. In general, ESR requires two external magnetic fields: a static field (B^0) to split the spin states in energy and an oscillating field (B^1) with the frequency resonant to the splitting energy. However, spin manipulation methods relying on real magnetic fields—much broader than the size of individual electrons—are energetically inefficient and unsuitable for future device applications. One of SOI-based ESR set-ups for spin manipulation is shown in Fig. 10(a). Quantum dot is formed in an InAs wire between two gate electrodes. In addition to static magnetic field B_{ext}^0 , SOI induces an oscillating B_{eff}^1 when an electron continuously moves back and forth by using time-dependent gate voltages V_{g1} and V_{g2} . Spin manipulations based on SOI-induced ESR have been realized by using semiconductor narrow wires, quantum dots and winding channels.

A ballistic spin resonance (BSR) was realized by utilizing oscillating field induced by the Rashba and Dresselhaus SOIs driven by the free motion of electrons that bounce at frequencies of tens of GHz in high mobility GaAs narrow channels (Frolov et al., 2009). BSR is manifested as a strong suppression of spin relaxation length when the motion of electrons is in resonance with spin precession.

Manipulation of single spins is essential for spin-based quantum information processing. Electrical control instead of magnetic control is particularly important for this purpose, because electric fields are easy to generate locally on-chip. Novak et al. experimentally realized coherent control of a single-electron spin in a GaAs/AlGaAs gate-defined quantum dot using an oscillating electric field generated by a local gate (Nowack et al., 2007).

Nadj-Perge et al. (2010) implemented a SO quantum bit (qubit) in an InAs nanowire, and realized fast qubit rotations and universal single-qubit control using electric fields; the qubits are hosted in single-electron quantum dots that are individually addressable. The authors claim that nanowires offer various advantages for quantum computing; they can serve as one-dimensional templates for scalable qubit registers, and it is possible to vary the material even during wire growth. Rabi frequencies exceeding 100 MHz were demonstrated in InSb nanowires (Van den Berg et al., 2013).

The demonstration of SO qubits coupled to superconducting resonators paves the way for a scalable quantum computing architecture. Circuit quantum electrodynamics (cQED) allows spatially separated superconducting qubits to interact via a superconducting microwave cavity that acts as a “quantum bus,” making possible two-qubit entanglement and the implementation of simple quantum algorithms. Petersson et al. (2012) combine the cQED architecture with spin qubits by coupling an InAs nanowire double quantum dot to a superconducting cavity. The demonstration of SO qubits coupled to superconducting resonators paves the way for a scalable quantum computing architecture.

Fig. 10 (a) An SOI-based ESR example. An electron confined in quantum dot(Q-dot) is moving back and forth by time dependent gate voltages V_{g1} and V_{g2} , leading to oscillating effective magnetic field B_{eff}^1 . Frequency of the oscillation field should be resonant with spin splitting energy induced by static external magnetic field B_{ext}^0 to manipulate the spin in Q-dot. (b) SOI in a winding channel induces effective static field B_{eff}^0 and oscillating field B_{eff}^1 . These fields are created when electron spins are carried by surface acoustic waves along the winding channel. H. Sanada, Y. Kunihashi, H. Gotoh, K. Onomitsu, M. Kohda, J. Nitta, P. V. Santos and T. Sogawa (2013) Manipulation of mobile spin coherence using magnetic-field-free electron spin resonance. *Nature Physics* 9: 280.

For ESR experiments using the SOIs so far, the spin splitting energies are induced by an external Zeeman field (or local ferromagnet) and oscillating resonant SOI fields driven by ac electric fields. Sanada et al. (2013) have demonstrated an alternative approach where the SOI of trajectory-controlled electrons induces effective static field B_{eff}^0 and oscillating field B_{eff}^1 . These fields are created when electron spins are carried by surface acoustic waves along winding semiconductor channels as shown in Fig. 10(b). The resultant spin dynamics—mobile spin resonance—is equivalent to the usual ESR but requires neither static nor time-dependent real magnetic fields to manipulate electron spin coherence.

Conclusion

Rashba SOI in semiconductor heterostructures is not materials constant but its strengths can be tuned by the design of QWs and an external gate voltage. Electrical spin generation, manipulation, and detection are prerequisite for future spintronics, and these spin functionalities can be realized solely by utilizing SOI. Spin polarized carriers have been generated by spin Hall effect and Stern-Gerlach spin filter. Both inverse spin Hall effect and spin filter can be also utilized for electrical spin detection. The electrical control of the magnetization direction of small magnets is currently among the most active areas in spintronics due to its interest for memory, logic and data storage applications. Spin-orbit torque (SOT) was first observed in (Ga,Mn)As (Chernyshov et al., 2009) where strained zinc-blende structure is responsible for the emergence of linear Dresselhaus SOI. SOT induced by spin Hall effect and Rashba-Edelstein effect are of importance for magnetization reversal of ferromagnets placed adjacent to SOI materials. Quantum spin Hall effect is discovered in HgTe/CdTe QWs by band inversion due to strong SOI. The quantized conductance is caused by the edge states where opposite spin-polarized currents are counter-propagating.

Gate controlled spin precession is confirmed in AC spin interference devices. This electrical control of spin precession is a basis of spintronics devices such as spin-FET. SOI-based ESR techniques are developed by using ac-electric fields for spin manipulations. Furthermore, magnetic-field-free ESR techniques based on SOI are demonstrated and can be applicable for quantum information process. Generation of both static and oscillating SOI effective fields is possible in an optimized winding channel since the SOI induced field is momentum dependent. Although SOI is an origin of spin relaxation, long spin coherence in the PSH state has been realized by making Rashba and Dresselhaus SOI equal strength. It should be emphasized that the concept of SOI demonstrated in semiconductors has inspired metal spintronics devices such as magnetization reversal using SOT, discoveries of new topological materials and innovative concepts such as Majorana fermions (Manchon et al., 2015).

Abstract

Spintronics has become a broad and important research field that intersects with magnetism, nano-electronics, and materials science. Its overarching aim is to provide a fundamental understanding of spin-dependent phenomena in solid-state systems that can enable a new generation of spin-based logic devices. Over the past decade, graphene and related 2D van der Waals crystals have taken center stage in expanding the scope and potential of spintronic materials. Their distinctive electronic properties and atomically thin nature have opened new opportunities to probe and manipulate internal electronic degrees of freedom. Purely electrical control over conduction-electron spins can be attained in graphene-transition metal dichalcogenide heterostructures, due to proximity effects combined with graphene's high electronic mobility. Specifically, graphene experiences a proximity-induced spin–orbit coupling that enables efficient spin-charge interconversion processes; the two most well-known and at the forefront of current research are the spin Hall and inverse spin galvanic effects, wherein an electrical current yields a spin current and nonequilibrium spin polarization, respectively. This article provides an overview of the basic principles, theory, and experimental methods underpinning the nascent field of 2D material-based spintronics.

Key points

This chapter aims to achieve the following:

- Provide a brief historic overview of how spintronics developed before and after the discovery of graphene,
- Discuss the various properties of the 2D honeycomb materials at the heart of spintronics in van der Waals heterostructures,
- Outline how the electronic structure of 2D monolayers, such as graphene, is altered by proximity-induced spin–orbit coupling using a tight-binding formalism informed by a symmetry analysis,
- Construct a low-energy theory representative of the van der Waals heterostructures used in realistic spintronic devices,
- Introduce the idea of spin–charge interconversion: how an electrical current can generate a macroscopic spin current or spin polarization, and vice versa,
- Present the framework of linear response theory used in the mathematical description of the spin Hall and inverse spin galvanic effects,
- Explain how spin–charge interconversion processes can be detected via electrical means.

Abbreviations

2DEG	Two-dimensional electron gas
BR	Bychkov–Rashba
CEE	Collinear Edelstein effect
DOF	Degree of freedom
FM	Ferromagnet or ferromagnetic

hBN	Hexagonal boron nitride
ISGE	Inverse spin galvanic effect
ISHE	Inverse spin Hall effect
KM	Kane–Mele
SdH	Shubnikov–de Haas
SGE	Spin galvanic effect
SHE	Spin Hall effect
SOC	Spin–orbit coupling
SOT	Spin–orbit torque
SV	Spin-valley
TB	Tight binding
TMD	Transition metal dichalcogenide
vdW	van der Waals
WAL	Weak localization
WL	Weak antilocalization

Introduction

Spintronics can be considered the magnetic counterpart to electronics whereby the transfer and processing of information can be conducted through the electron's spin degree of freedom (DOF), rather than or in addition to its electronic property of charge. Specifically, spintronics concerns itself with the electrical manipulation of the electron's spin and one of its first milestones was the observation of a spin-polarized current by [Tedrow and Meservey \(1973\)](#). Despite this and the first controlled injection of a spin-polarized current into a nonmagnetic material being achieved in 1985 ([Johnson and Silsbee, 1985](#)), it was only in 1988 that spintronics began to bloom and flourish into the field we know today. What sparked this scientific boom was the independent observation of a giant magnetoresistance attributed to the relative orientation of the ferromagnetic (FM) layers in Fe-Cr-based systems by [Baibich et al. \(1988\)](#) and [Binasch et al. \(1989\)](#).

Since the Nobel prize winning discovery of giant magnetoresistance, initial efforts in the field focused on spin valve setups to study how the electron's spin would diffuse and relax through a normal metal when injected via a spin-polarized current using an FM contact. However, a more exotic method of spin current generation had already been proposed in 1971 by [Dyakonov and Perel \(Dyakonov and Perel, 1971a,b; Sinova et al., 2015\)](#), the *spin Hall effect* (SHE), where the application of an electrical current would yield a perpendicular pure spin current without the need for magnetic materials. The origin of this effect can be found in the asymmetric scattering of electrons based upon their spin due to the presence of spin–orbit coupling (SOC). Initially observed in 2004 via optical methods ([Kato et al., 2004](#)), the SHE and its inverse (ISHE) have become paradigmatic phenomena in spintronics due to their lack of reliance upon magnetic components. A major focus for the application of the SHE is in low-power magnetic memory devices, where the manifestation of a spin current results in a spin accumulation, and hence a net spin polarization, which can exert a torque on the magnetization of a nearby FM. With a large enough spin accumulation, dramatic effects like magnetization switching can be induced. Clearly, with the use of a simple electrical current, we can manipulate the spin of charge carriers in a material and induce interesting nonequilibrium phenomena at interfaces between materials, thus yielding important applications in modern information technology.

In addition to spin current, another major concept in spintronics is *spin texture*: the momentum dependence of the transport electrons' spin within a solid. In many low-dimensional systems and at heterostructure interfaces, the enhancement of the relativistic spin–orbit interaction is key to generating nontrivial spin textures that give rise to a plethora of phenomena, ranging from the spin-momentum-locked surface states in topological insulators to the topologically protected real-space spin textures seen in chiral magnets, such as skyrmions and spin spirals. Of particular interest is the emergence of a spin polarization, as in the SHE, but without a resulting spin current. This effect, the sole spontaneous generation of a spin polarization via application of an electric current, is known as the *inverse spin galvanic effect* (ISGE), though in some literature it may also be referred to as the Rashba–Edelstein or Edelstein effect. Based upon Bychkov–Rashba-type SOC ([Bychkov and Rashba, 1984](#)), arising when the mirror symmetry about a given plane is broken, this effect was initially predicted in two-dimensional electron gases (2DEGs) in semiconductor heterostructures in 1989 ([Aronov and Lyanda-Geller, 1989](#); [Edelstein, 1990](#); [Aronov et al., 1991](#)) but remained unobserved in experiment until 2002, when its reciprocal effect (i.e., spin-to-charge conversion) was observed ([Ganichev et al., 2002](#)). Combining both the SHE and ISGE, we find ourselves in a position with great control over the motion and net orientation of the electron spins in materials. However, to truly construct realistic devices using a spin-focused infrastructure, we must understand what makes an ideal material for providing such intricate control over spin. The two most important factors governing the effectiveness of spintronic devices are disorder and SOC: both mechanisms yield significant consequences on the transport range of electron spins and our control over them. While a larger SOC might ensure more efficient generation of spin currents and polarizations, it comes at the cost of faster spin dephasing and hence spin information is lost over a much shorter distance. In contrast, a weak SOC might allow for long range transport, but results in less efficient charge-to-spin conversion. Similarly, disorder can also change the efficiency of spin–charge interconversion. In a pristine system, the only processes present will be those intrinsic to the system. However, upon the

inclusion of disorder, some intrinsic mechanisms are completely suppressed in favor of extrinsic mechanisms. Furthermore, spin–orbit active impurities can have similar effects to including a SOC into the system, due to their ability to change an electron's spin orientation. Clearly, there is a balancing act to be handled in constructing ideal spintronic devices with both disorder and SOC acting as the tuning knobs.

Prior to 2004, experiments studying spin transport focused primarily on 2DEGs realized in a multitude of systems including thin metallic films (Jedema et al., 2001), permalloys (Steenwyk et al., 1997; Dubois et al., 1999), and semiconductor heterostructures (Yang et al., 1994; Kikkawa and Awschalom, 1999; Ohno et al., 1999; Malajovich et al., 2000). In most cases, spin information was passed into the system by either a spin-polarized charge current, or via optical excitation of a semiconductor resulting in a spin imbalance of the conduction band. Despite these initial endeavors, the electrical processing of spin-encoded information was hindered by the difficulty of combining effective spin control with large enough spin lifetimes. However, with the discovery of graphene in 2004 as the first truly 2D, that is, atomically thin, solid state system, a new epoch dawned in spintronics. It was quickly established that bare graphene offered the largest spin diffusion lengths of any material to date, with many reports finding $l_s \sim 1 - 20 \mu\text{m}$, courtesy of the weak intrinsic spin–orbit and hyperfine interactions of sp^2 hybridized carbon.

Naturally, graphene's extremely small intrinsic SOC makes it difficult to have precise electrical control over the net spin orientation, but does allow for long-distance spin-information transfer. However, with the many advances in nanofabrication over the past two decades and the isolation of other 2D materials, such as transition metal dichalcogenides (TMDs), layer-by-layer assemblies of 2D materials have been imagined and constructed with the ability to alter the net behavior of the composite system based purely on the individual layers used. Thus the concept of bespoke devices combining the desirable properties of different materials has become possible in the form of van der Waals (vdW) heterostructures.

What single 2D crystals lack, vdW heterostructures may offer a way to access by enhancing certain properties by matching an appropriate set of materials. Through simple proximity effects, the properties absent or deemed too weak in the original isolated crystal can be enhanced. Semiconducting TMDs, such as MoS_2 and WTe_2 , are a classic example of this; due to their composition involving transition metal atoms, they naturally possess a large SOC. By stacking this with a graphene monolayer, the electrons of the graphene sheet will experience a *proximity-induced SOC effect* due to their ability to now hop between the two layers. Furthermore, graphene's transport nature is not jeopardized by the proximity of the TMD since the low-energy states of graphene lie well within the TMD band gap. Consequently, transport is still dominated by the more conductive graphene layer, though the electronic states are now endowed with a substantial SOC. The typical size of these induced SOC's is up to order 10 meV (Wang et al., 2019), which is three orders of magnitude larger than the intrinsic SOC present in regular graphene (Kane–Mele type of order 10 μeV (Sichau et al., 2019)). The specific values of the SOC's depend on the choice of TMD partner and can be further tuned by means of external pressure (Fulop et al., 2021). This dramatic change from an isolated crystal's properties with the introduction of material partners is what makes vdW heterostructures the modern candidates par excellence for many condensed matter experiments.

Graphene and van der Waals heterostructures

Formed by stacking atomically thin layers of hexagonally packed atoms with weak vdW forces binding neighboring layers together, Fig. 1a (Geim and Grigorieva, 2013), vdW heterostructures constitute a specific class of 2D materials. Given the breadth of materials with 2D behavior—encompassing semiconductors, insulators, and semimetals—which can be exfoliated down to a monolayer, it is no surprise that the variety of vdW heterostructures is equally diverse. Furthermore, the electronic properties of such 2D compounds are sensitive to the number of layers, stacking sequence, and atomic coordination, while also being tunable “on-demand” through the controlled application of strain and electric fields (Castro Neto et al., 2009; Wang et al., 2012; Yun et al., 2012).

Monolayer graphene presents itself as a zero-gap semiconductor with a linear dispersion relation for both electrons and holes, whose unit cell consists of two distinct lattice sites that are individually referred to as A and B sublattices (Fig. 1b). The band structure of graphene is characteristic of *massless chiral Dirac fermions*, which derives from the sp^2 network of carbon atoms forming a honeycomb lattice with preserved inversion symmetry (Fig. 1b), whose presence gives rise to graphene's notable electronic properties (Castro Neto et al., 2009). Other 2D materials relevant to vdW heterostructures include (i) hexagonal boron nitride “hBN,” an insulator (ii) bilayer graphene, a zero-gap semiconductor with parabolic band dispersion; and (iii) group-VI dichalcogenides, direct band-gap semiconductors with strong SOC.

What makes a material useful in vdW heterostructures varies from material to material. The band gap opening in polyatomic compounds (e.g., hBN) is a direct consequence of broken inversion symmetry. The electronic band gap in monolayer hBN is about 7 eV, making it an insulating analog of graphene. The small lattice mismatch between hBN and graphene (about 1.8%) allows for easy integration in graphene-based devices using dry transfer techniques. hBN encapsulation yields major improvements in the electronic mobility of graphene-based devices and is currently the gold standard for the fabrication of high-performance vdW heterostructures. In lateral spin transport experiments, the hBN encapsulation of graphene has enabled a 10-fold increase in room-temperature spin lifetimes compared to devices using the now obsolete silicon oxide substrates (Drögele et al., 2014). The hBN induces an orbital gap in graphene (Fig. 2a), which results from virtual interlayer hopping processes between carbon sites in graphene and the distinct chemical species occupying the A and B sublattices of the partnered hBN layer.

Fig. 1 (a) Vertical heterostructure built from 2D crystals. (b) The honeycomb lattice composed of two triangular Bravais lattices (top right corner shows the first Brillouin zone with two inequivalent Dirac points, $K_{\pm}$). The nearest-neighbor vectors read as $\delta_i = a (\sin \alpha_i, -\cos \alpha_i)^T$, where a is the bond length and $\alpha_i = \frac{2\pi}{3}(i - 3)$ and $i = 1, 2, 3$. (a) Reprinted with permission from Geim AK and Grigorieva IV (2013) Van der Waals heterostructures. Nature 499(7459): 419–425. <https://doi.org/10.1038/nature12385>.

Fig. 2 (a) Low-energy dispersion of a honeycomb monolayer with a small orbital gap ($m \neq 0$). (b) Lifting of spin degeneracy due to symmetry breaking SOC (arrows indicate different spin states).

Bilayer graphene can exist in Bernal-stacked “AB” form, with atoms on opposite layers stacked on top of each other in a staggered configuration, or, less frequently, in the “AA” form, with sublattices in adjacent layers perfectly aligned (Liu et al., 2009). Similar to monolayer graphene, its conduction and valence bands touch at the Brillouin zone corners (Fig. 2a); however, low-energy excitations around the Fermi points are associated with quadratic energy dispersion (McCann and Fal’ko, 2006; Guinea et al., 2006). The finite density of states near the Fermi level exacerbate the effect of interactions leading to rich broken symmetry states even in the absence of external fields (Zhang et al., 2010; Vafeek and Yang, 2010; Nandkishore and Levitov, 2010; Weitz et al., 2010). Individual layers in AB bilayer graphene can be addressed separately allowing important device functionalities, including band gap opening through gating (McCann, 2006; Castro et al., 2007). Of particular interest for spintronics is the ability to fine-tune both the SOC (proximity with a TMD) and exchange interaction (proximity with an FM) experienced by the electrons. Only the layer that is the immediate neighbor to a partner material will experience significant proximity effects. Therefore, by applying an electric field perpendicular to the graphene bilayer, the electron density of each layer can be adjusted, which in turn changes the proximity-

induced SOC and exchange interaction experienced by the electrons by shifting them toward or away from the partner material (Zollner et al., 2020).

Group-VI dichalcogenides [MX₂ (M = Mo, W; X = S, Se, Te)] can be either trigonal-prismatically or octahedrally coordinated (so-called 2H and 1T phases, respectively). These polytypic structures have vastly different electronic properties: while TMDs of the 2H-MX₂ type are large-gap semiconductors, 1T-MX₂ are predominantly metals (Mattheiss, 1973; Eda et al., 2012; Voiry et al., 2015). 2H-TMD monolayers have direct band gaps in the near-infrared to the visible region, which make them well suited for a broad range of applications in optoelectronics and photonics (Mak and Shan, 2016). Owing to ultimate (2D) quantum confinement, electrons and holes are tightly held together which is responsible for enhanced light-matter interactions. Excitons have typical binding energies of 0.5 eV, which strongly impact the spin and optoelectronic properties of semiconducting TMDs (Wang et al., 2018). Moreover, the spin-valley locking of energy states in the vicinity of $K_{\pm}$ points, stemming from lack of inversion symmetry, lead to spin-valley-dependent optical transition rules (Wang et al., 2012), which enable the addressing of individual valleys with circularly polarized light. The spin-valley coupling in TMDs has been explored to convert optically driven valley currents into charge currents via the inverse valley Hall effect (Mak et al., 2014). In free-standing conditions, the 1T phase undergoes a spontaneous lattice distortion to a semiconducting phase dubbed 1T', which supports robust nontrivial topological behavior (quantum spin Hall effect) (Qian et al., 2014; Tang et al., 2017; Wu et al., 2018; Shi et al., 2019).

The weak vdW forces between planes of 2D crystals offer a practical route for band structure design. A remarkable example is "twisted" bilayer graphene, where the two graphene monolayers forming bilayer graphene are offset from one another by a simple rotation about the out-of-plane axis (Lopes dos Santos et al., 2007), in addition to their stacking arrangement. For "magic angle" twisted bilayer graphene, the superlattice created by the two graphene sheets leads to strong renormalization of the band structure, which can exhibit flat bands at the Fermi level, leading to possible strongly correlated insulating states in the ultimate 2D (atomically thin) limit (Cao et al., 2018).

With the above discussion of different 2D systems and their various combinations, it is clear that vdW heterostructures offer a route toward 2D designer materials. The exact combination of the individual layers is dictated by the purpose of the device being constructed. This is particularly relevant when trying to study and apply the SHE and ISGE from a technological perspective. The specifics behind these phenomena are discussed toward the end of this article while the effect of proximity-induced SOC shall be covered shortly.

Honeycomb monolayers: A tight-binding description

The distinctive electronic properties of 2D layered materials and the special role played by the sublattice DOF can be best appreciated within a tight-binding (TB) model of electrons hopping on a honeycomb lattice (Fig. 1b). The minimal Hamiltonian (without SOC) reads as

$$H_{2D} = -t \sum_{\langle i,j \rangle} (a_i^\dagger b_j + \text{H.c.}) + m \sum_i (a_i^\dagger a_i - b_i^\dagger b_i) \quad (1)$$

where the fermionic operator a_i (b_i) annihilates a quasiparticle on site i belonging to sublattice $A(B)$, t is the nearest neighbor hopping energy ($t \approx 2.8$ eV in graphene Castro Neto et al., 2009), and $\langle i, j \rangle$ denotes the sum over nearest neighbors. The second term describes a staggered on-site energy with amplitude $m = (\epsilon_A - \epsilon_B)/2$ and is relevant for noncentrosymmetric 2D crystals (e.g., $m \approx 3.5$ eV in hBN (Román et al., 2021) and $m \approx 0.7 - 0.9$ eV in semiconducting TMDs (Xiao et al., 2012)), as well as graphene-based heterostructures displaying Moiré superlattice effects (Dean et al., 2010; Jung et al., 2015; Wallbank et al., 2015).

This tight-binding Hamiltonian provides a starting point for understanding the low-energy properties of prototypical 2D materials. The energy bands are obtained by means of the Fourier transform a_i (b_i) = $N^{-1} \sum_{\mathbf{k}} e^{-i\mathbf{k} \cdot \mathbf{r}_i} a_{\mathbf{k}}$ ($b_{\mathbf{k}}$), where $\mathbf{k} = (k_x, k_y)^T$ is the 2D wavevector and N is the number of sites in each sublattice ($N = N_A = N_B$). After straightforward algebra, one finds

$$H_{2D} = \sum_{\mathbf{k}} \begin{pmatrix} a_{\mathbf{k}}^\dagger & b_{\mathbf{k}}^\dagger \end{pmatrix} \begin{pmatrix} m & \phi^*(\mathbf{k}) \\ \phi(\mathbf{k}) & -m \end{pmatrix} \begin{pmatrix} a_{\mathbf{k}} \\ b_{\mathbf{k}} \end{pmatrix}, \quad (2)$$

with the geometric form factor

$$\phi(\mathbf{k}) = -t \sum_{a=1,2,3} e^{i\mathbf{k} \cdot \boldsymbol{\delta}_a}, \quad (3)$$

where the bond vectors, $\boldsymbol{\delta}_a$, are defined in the caption of Fig. 1. The energy dispersion is readily obtained as

$$E(\mathbf{k}) = \pm \sqrt{t^2 |\phi(\mathbf{k})|^2 + m^2}, \quad (4)$$

where the sign $\pm$ selects positive (negative) energy branch of the spectrum. A band structure representative of graphene with a sublattice staggered potential is shown in Fig. 2a. Of particular note is the appearance of local extrema in the spectrum at the corners of the Brillouin zone, $K_{\pm}$, where $E = \pm m$, known as Dirac points. In this example, the small orbital gap ($m \ll t$) could be due to use of a lattice-matching substrate (e.g., hBN). At half-filling, the negative energy states are completely filled, and hence the low-energy physics is controlled by excitations about the Dirac points (the region around a Dirac point is known as a valley). For

semiconducting TMDs and hBN, the staggered on-site energy is comparable to (or larger than) t , resulting in sizable orbital gaps at the Dirac points. The generalization of this Hamiltonian to describe the strong intrinsic SOC inherent in semiconducting TMDs, as well as symmetry breaking SOC in vdW heterostructures, is presented in the next section. While the extension of the effective TB model to multilayers (e.g., bilayer graphene) is straightforward, the complete details are beyond the scope of this article, though the interested readers can find details in [Peres \(2010\)](#) and [McCann and Koshino \(2013\)](#).

Honeycomb monolayers: SOC interactions

The electronic structure of 2D materials containing heavy elements is strongly modified by spin-orbit effects generated by the periodic crystal potential. In the nonrelativistic approximation to the Dirac equation, the intrinsic spin-orbit interaction reads as

$$H_{\text{SO}} = -\frac{\hbar}{4m_e^2 c^2} \mathbf{s} \cdot (\mathbf{p} \times \nabla V), \quad (5)$$

where $V(\mathbf{x})$ is the periodic crystal potential, $\mathbf{p}$ is the momentum operator, m_e is the electron mass, and $\mathbf{s}$ is the vector of Pauli matrices describing spin-1/2 particles (i.e., acting on the spin DOF). The (spin-dependent) hopping generated by Eq. (5) can be obtained by exploring time-reversal symmetry (T) and the crystal symmetries. The most general H_{SO} for honeycomb lattices may therefore be written as

$$H_{\text{SO}}^T = \sum_{\langle i, j \rangle} \left(\hat{a}_i^\dagger T_{ij}^{ab} \hat{b}_j + \hat{b}_i^\dagger T_{ij}^{ba} \hat{a}_j \right) + \sum_{\langle\langle i, j \rangle\rangle} \left(\hat{a}_i^\dagger T_{ij}^{aa} \hat{a}_j + \hat{b}_i^\dagger T_{ij}^{bb} \hat{b}_j \right), \quad (6)$$

where $\hat{a}_i^\dagger/\hat{a}_i$ ($\hat{b}_j^\dagger/\hat{b}_j$) are creation/annihilation operators for the $A(B)$ sublattice with a 2-component spinor structure acting on spin space, $T_{ij}^{(\zeta)}$ (with $\zeta = aa, ab, bb$) are spin-dependent hopping coefficients with a 2×2 complex matrix structure satisfying $T_{ij}^\zeta = [T_{ji}^\zeta]^\dagger$, and $\langle\langle i, j \rangle\rangle$ denotes the sum over next-nearest neighbors. The neglect of hoppings beyond next-nearest neighbors in Eq. (6) is justified given the exponential decay of matrix elements with the distance. Note that on-site spin-dependent terms, such as $\hat{a}_i^\dagger s_z \hat{a}_i$, change sign under T and thus are not allowed.

The symmetries of the system are contained within the $T_{ij}^{(\zeta)}$. Expansion of the spin hopping matrices into elements of the $\text{SU}(2)$ spin-algebra yields

$$T_{ij} = \omega_{ij}^x s_x + \omega_{ij}^y s_y + \omega_{ij}^z s_z, \quad (7)$$

where sublattice superscripts have been omitted. The antiunitary operator enacting T is given by $\Theta = i s_y K$, where K denotes complex conjugation. The requirement, $T_{ij} = \Theta T_{ij} \Theta^{-1}$, leads to the following constraint: $\omega_{ij}^\alpha = -(\omega_{ij}^\alpha)^*$ (with $\alpha = x, y, z$). As such, the coefficients of spin-dependent hopping mediated by H_{SO} are purely imaginary. The full set of spin-orbit interactions up to next-nearest neighbors are shown in [Fig. 3](#), where the allowed hoppings are dictated by the point group symmetry. For example, D_{6h} -invariant Hamiltonians (e.g., flat pristine graphene) only permit spin-conserving next-nearest neighbor hoppings. This is the result of three symmetries. First, mirror inversion about the plane, Σ_{xy}^h , which reverses the sign of x - and y -components in Eq. (7), forbids all spin flip processes, $\omega_{ij}^{(x,y)} = 0$. Second, the mirror symmetry Σ_{yz}^d , which sets $y \rightarrow -y$ and consequently reverses the sign of s_z in Eq. (7), ensures that $\omega_{ij}^z = 0$ for all in-plane vertical hoppings, which are naturally nearest neighbor processes. Finally, combining the Σ_{yz}^d mirror symmetry with 6-fold rotational symmetry about the z -axis, we see that the vertical hoppings must map onto the other nearest neighbor hoppings and hence they too must vanish.

More generally, when space inversion or horizontal reflection symmetries are broken, other terms are allowed. Of particular relevance is the C_{3v} point group, given that it is a common subgroup of D_{3h} (e.g., hBN and TMD monolayers), D_{3d} (e.g., rippled graphene and Si- and Ge-based graphene analogs), and C_{6v} (e.g., graphene on a nonlattice-matched substrate) and hence defines the most general class of Hamiltonians compatible with the honeycomb lattice symmetries ([Saito et al., 2016](#); [Kochan et al., 2017](#)). Altogether, C_{3v} -invariant models allow for 3 types of SOC

$$H_{\text{SO}}^{C_{3v}} = \frac{i}{3\sqrt{3}} \sum_{\langle\langle i, j \rangle\rangle} v_{ij} \left(\lambda_A \hat{a}_i^\dagger s_z \hat{a}_j + \lambda_B \hat{b}_i^\dagger s_z \hat{b}_j \right) + \frac{2i}{3} \sum_{\langle i, j \rangle} \left[\lambda \hat{a}_i^\dagger (\mathbf{s} \times \mathbf{d}_{ij})_z \hat{b}_j + (b \leftrightarrow a) \right] \\ + \frac{2i}{3} \sum_{\langle\langle i, j \rangle\rangle} \left[\lambda_{nm}^A \hat{a}_i^\dagger (\mathbf{s} \times \mathbf{d}_{ij})_z \hat{a}_j + \lambda_{nm}^B \hat{b}_i^\dagger (\mathbf{s} \times \mathbf{d}_{ij})_z \hat{b}_j \right], \quad (8)$$

namely, spin-conserving sublattice-resolved SOC, $\lambda_{A(B)}$, Bychkov-Rashba (BR) interaction, λ , and spin-flipping sublattice-resolved SOC, $\lambda_{nm}^{A(B)}$. Here, $\mathbf{d}_{ij}$ is the unit vector along the line segment connecting site i and j while $v_{ij} = \pm 1$ distinguishes between clockwise and anticlockwise electron hopping, respectively.

The spin-conserving SOC (first term in [Eq. 8](#)) is a fingerprint of pseudospin-spin coupling in 2D layered materials. Two cases are of noteworthy interest: (i) centrosymmetric crystals, where only a spin conserving SOC is permitted with $\lambda_A = \lambda_B$, as is the case in pristine graphene (D_{6h}) discussed above, and graphene-like materials with D_{3d} point group, and (ii) systems with broken inversion symmetry leading to sublattice-resolved SOC ($\lambda_A \neq \lambda_B$), as seen, for example, in 2H-TMD monolayers (D_{3h}) and graphene-TMD

Fig. 3 Spin-orbit hopping terms compatible with subgroups of D_{6h} . Horizontal (h), vertical (v), and dihedral (d) reflections are shown (bottom, middle). Black (white) arrows indicate spin-conserving (spin-flip) hoppings. D_{6h} , D_{3h} , and D_{3d} -invariant systems (top panel) admit next-nearest hoppings. C_{6v} - and C_{3v} -invariant systems (bottom panel, right and left) allow for nearest neighbor spin-flip hopping.

heterostructures (C_{3v}). The BR interaction generated by the nearest-neighbor spin-flip hoppings (second term in Eq. 8) signals the lack of mirror inversion symmetry, Σ_{xy}^h , associated with reduction of the point group from D_{6h} to C_{6v} which may occur through interfacial effects in heterostructures or via application of an electric field perpendicular to the 2D plane. Finally, next-nearest-neighbor spin-flip processes, parameterized by the couplings $\lambda_{nn}^{A(B)}$ (third term in Eq. 8) are also allowed in systems lacking out-of-plane reflection symmetry, Σ_{xy}^h , such as graphene-based vdW heterostructures or graphene placed on a generic substrate. Note that when the in-plane inversion symmetry is also broken, these processes become sublattice-resolved ($\lambda_{nn}^A \neq \lambda_{nn}^B$). This occurs, for example, in graphene-TMD heterostructures.

Honeycomb monolayers with proximity-induced SOC: Continuum theory

The low-energy electronic structure of 2D materials can be conveniently modeled using a (long-wavelength) continuum description. Expanding the geometric form factor (Eq. 3) to first order around each Dirac point, $\mathbf{K}_{\pm} = 4\pi/(3\sqrt{3}a)(\pm 1, 0)^T$, that is $\phi_{\pm}(\mathbf{k}) \simeq (3ta/2)(\pm k_x + ik_y)$, yields the effective single-particle Hamiltonian $\mathcal{H}_{0k} = \hbar v(\tau_z \otimes \sigma_x k_x + \tau_0 \otimes \sigma_y k_y) \otimes s_0 + m\tau_0 \otimes \sigma_z \otimes s_0$ when written in the conventional basis, $|\psi\rangle = (K_+, K_-)^T \otimes (A, B)^T \otimes (\uparrow, \downarrow)^T$. Here $\mathbf{k}$ is the 2D wavevector measured with respect to a Dirac point, $v = 3at/2\hbar$ is the Fermi velocity of massless Dirac fermions, s_0 is the identity matrix acting on the spin DOF, and σ_i and τ_i are the Pauli matrices supplemented with identity acting on sublattice and valley DOFs, respectively. This low-energy Hamiltonian admits an even simpler and more elegant form when written using the *valley basis*, $|\psi\rangle = (K_+A, K_+B, -K_-B, K_-A)^T \otimes (\uparrow, \downarrow)^T$, that is, $\mathcal{H}_{0k} = \tau_0 \otimes H_{0k} \otimes s_0$, with

$$H_{0k} = -i\hbar v \boldsymbol{\sigma} \cdot \mathbf{k} + m\sigma_z. \quad (9)$$

The Dirac-Weyl equation (Eq. 9) governs the low-energy properties of honeycomb monolayers with low SOC and has been extensively used in investigations of opto-electronic and transport phenomena in single-layer graphene (Peres, 2010; McCann and Koshino, 2013). For ease of notation, the writing of the tensor product between matrices acting on different DOFs is omitted from here onward.

The spin-orbit interactions in the continuum can be derived by expanding the Fourier transformed TB Hamiltonian (Eq. 8) around the K points. Here, as in the previous section for the full TB Hamiltonian, $\mathcal{T}$ and unitary (spatial) symmetries are exploited so as to constrain the allowed spin-orbit terms in the continuum theory. The time-reversal operation reverses spins $s \rightarrow -s$ and swaps valleys (as momentum reversal sends $K_+ \leftrightarrow K_-$). Since the time reversal operator is antiunitary, the σ_y pseudospin operator is

also affected, $T: \sigma_x \rightarrow \sigma_x, \sigma_y \rightarrow -\sigma_y, \sigma_z \rightarrow \sigma_z$. Exploiting the T -symmetry transformations, one finds that there are $4 \times 3 = 12$ possible terms

$$\mathcal{H}_{\text{SO}}^T = \sum_{i=x,y,z} \left(\Delta^{(i)} \tau_0 \sigma_z + \lambda_x^{(i)} \tau_0 \sigma_x + \lambda_y^{(i)} \tau_0 \sigma_y + \omega^{(i)} \tau_z \sigma_0 \right) s_i. \quad (10)$$

Direct inspection of Eq. (10) shows that the majority of SOC terms lead to anisotropic energy dispersion, and hence are incompatible with the C_{3v} point group symmetry. To preserve the continuous rotational symmetry of the low-energy theory about each Dirac point, the Hamiltonian within each valley should commute with the generator of rotations within the 2D plane for that valley (the total angular momentum operator). In the valley basis, the total angular momentum is independent of the valley index and takes the form

$$J_z = -i \hbar \partial_\phi \tau_0 \sigma_0 s_0 + \frac{\hbar}{2} (\tau_0 \sigma_z s_0 + \tau_0 \sigma_0 s_z), \quad (11)$$

where ϕ is the azimuthal angle. The first term of J_z is simply the orbital angular momentum while the s_z piece is the usual spin contribution. The σ_z term arises from spin-like sublattice DOF and is therefore characteristic of vdW materials. The requirement of J_z 's commutation with the Hamiltonian yields $\Delta^{(x,y)} = \omega^{(x,y)} = \lambda_{x(y)}^z = 0$, $\lambda_x^{(y)} = -\lambda_y^{(x)}$ and $\lambda_x^{(x)} = \lambda_y^{(y)}$. One of such terms, a Dresselhaus-type SOC, $\lambda_x^{(x)} \tau_0 (\sigma_x s_x - \sigma_y s_y)$, breaks the mirror reflection symmetry about the yz plane, rendering atomic sites within the same sublattice inequivalent, and is thus forbidden in C_{3v} invariant systems.

The full C_{3v} -invariant low-energy Hamiltonian in momentum space is therefore

$$H_k^{C_{3v}} = \hbar v \tau_0 \boldsymbol{\sigma} \cdot \mathbf{k} s_0 + m \sigma_z + \Delta_{\text{KM}} \tau_0 \sigma_z s_z + \lambda_{\text{BR}} \tau_0 (\sigma_x s_y - \sigma_y s_x) + \lambda_{\text{sv}} \tau_z \sigma_0 s_z, \quad (12)$$

where the above couplings have a simple correspondence to the spin-hoppings of the TB model (Eq. 8)

$$\Delta_{\text{KM}} = \frac{\lambda_A + \lambda_B}{2}, \quad \lambda_{\text{sv}} = \frac{\lambda_A - \lambda_B}{2}, \quad \lambda_{\text{BR}} = \lambda. \quad (13)$$

The competition between the different spin-orbit energy scales in Eq. (12) influences the energy dispersion while also dictating the topological properties and the spin structure of the eigenstates. Kane-Mele SOC ($\Delta_{\text{KM}} \tau_0 \sigma_z s_z$) leads to spin-degenerate bands due to its spin-conserving nature, with the ability to drive the system into a topologically nontrivial phase when it dominates (Qian et al., 2014; Wu et al., 2018; Shi et al., 2019). However, in the honeycomb monolayer systems of interest here, including TMDs and graphene-based vdW heterostructures, the Kane-Mele SOC is negligible. In contrast, the spin-valley coupling ($\lambda_{\text{sv}} \tau_z \sigma_0 s_z$), also known as valley-Zeeman interaction, emerging from sublattice-resolved SOC, is generally significant and yields spin-split bands within each valley. Typically, λ_{sv} is of order 100 meV for semiconducting TMDs (intrinsic SOC) (Xiao et al., 2012) and 1 meV for graphene-TMD heterostructures (proximity-induced SOC) (Tiwari et al., 2022). The Bychkov-Rashba term, $\lambda_{\text{BR}} \tau_0 (\sigma_x s_y - \sigma_y s_x)$, arising at heterostructure interfaces, leads to spin admixture in the spin states, characterized by in-plane spin-momentum locking of the Bloch eigenstates. Similar to spin-valley SOC, this term results in spin-split bands distinguished by *spin helicity* rather than simple spin. The magnitude of this coupling is typically on the order of 1–10 meV, depending on the TMD used (Tiwari et al., 2022; Wang et al., 2019). The presence of significant Rashba coupling explains the recently observed large charge-to-spin conversion via the ISGE at room temperature (Offidani et al., 2017), as discussed later on in this article. Finally, it is worth noting that the sublattice-resolved spin-flip terms ($\lambda_{nm}^{A(B)}$) (see Eq. 8) are absent in the low-energy Hamiltonian (i.e., they appear at the next order in the small- $\mathbf{k}$ expansion), and as such have little impact on the transport physics of 2D honeycomb layers.

The dispersion relation associated with Eq. (12) consists of two pairs of spin-split Dirac bands. A typical energy dispersion relation for a graphene-TMD heterostructure with competing Rashba and spin-valley couplings is shown in Fig. 4a. The general electronic dispersion of C_{3v} invariant systems can be readily seen as

$$\varepsilon_\zeta(k) = \pm \sqrt{\hbar^2 v^2 k^2 + \Delta_\zeta^2(k)}, \quad (14)$$

where Δ_{KM} has been neglected due to its inherently small nature compared to other SOC energy scales, $k \equiv |\mathbf{k}|$, $\zeta = \pm 1$ is the *spin-helicity* index, and $\Delta_\zeta^2(k)$ is the SOC-dependent mass term,

$$\Delta_\zeta^2(k) = m^2 + \lambda_{\text{sv}}^2 + 2\lambda_{\text{BR}}^2 + 2\zeta \sqrt{(\lambda_{\text{BR}}^2 - m\lambda_{\text{sv}})^2 + \hbar^2 v^2 k^2 (\lambda_{\text{BR}}^2 + \lambda_{\text{sv}}^2)}. \quad (15)$$

The spin texture of the eigenstates (see Fig. 4b) can be cast in the following compact form

$$\langle \mathbf{s} \rangle_{\zeta \tau k} = -\zeta \varrho(k) (\hat{\mathbf{k}} \times \hat{\mathbf{z}}) + m_{\zeta \tau}^z(k) \hat{\mathbf{z}}, \quad (16)$$

where $\tau = \pm 1$ is the $K_\pm$ valley quantum number. The first term describes the spin winding of the electronic states generated by the BR effect (Rashba, 2009). The second term is due to breaking of sublattice symmetry ($\lambda_{\text{sv}} \neq 0$ or $m \neq 0$) and tilts the spins in the $\hat{\mathbf{z}}$ direction. Because of the Dirac nature of the charge carriers, the spin texture has a strong dependence upon the Fermi energy. In fact, the spins point fully out of the plane at the Dirac point, but acquire an in-plane component as k is increased. For $\hbar v k \gg \Delta_\zeta$, one finds $\rho(k) \simeq \cos \theta$ and $m_{\zeta \tau}^z(k) \simeq \sin \theta$, with $\theta = -\tau \arctan(\lambda_{\text{sv}}/\lambda_{\text{BR}})$. The tilting angle, θ , has opposite signs in different valleys by virtue of time-reversal symmetry. Furthermore, one observes two distinct electronic regimes. For energies within the spin gap (regimes Ia and Ib in Fig. 4), the Fermi surface has a *well-defined spin helicity*, a feature reminiscent of spin-momentum locking in

Fig. 4 (a) Energy dispersion near the Fermi level. Symmetry breaking SOC opens a spin gap. A small Mexican hat develops in the regime I due to the interplay of spin–valley coupling and Rashba SOC. (b) Tangential winding of the spin texture in regimes I (3D view) and II (top view).

topologically protected surface states (Schwab et al., 2011). Consequently, near-optimal charge-to-spin conversion is observed inside the spin gap via a large ISGE. In contrast, for energies outside the spin gap (regime II in Fig. 4), the spin helicity is no longer a well-defined concept, but the larger Fermi radius of the spin-majority band ($\zeta = -1$) nevertheless allows for a detectable ISGE (i.e., while the current-induced spin polarization arising from the two subbands have opposite signs, they do not cancel each other). These special features of the electronic and spin structure of proximitized 2D materials are ultimately responsible for the efficient current-driven spin polarization supported by graphene-TMD heterostructures (Offidani et al., 2017).

Relativistic spin–orbit coupled transport phenomena

Electronic signatures

As alluded to above, the presence of SOC in a material can drastically alter the transport properties of materials due to spin-charge inter-conversion effects. One of the earliest signatures of SOC-affected transport was measured in magnesium films (i.e., 2DEGs) (Bergman, 1982; Sharvin and Sharvin, 1981), where the electrical conductivity was seen to decrease upon the application of a magnetic field (i.e., a negative magneto-conductivity). This behavior can be traced back to the quantum interference between the many paths an electron can take when traveling through a disordered system. In the case of a material where SOC is absent, quantum interference leads to the coherent backscattering of electrons, thus yielding more localized states, and hence reduces the electrical conductivity in a phenomenon known as *weak localization* (WL). The application of a magnetic field here destroys the coherence of the backscattered electrons and hence inhibits WL. Therefore, a positive magneto-conductivity is a clear signature of WL.

In contrast, materials that are SOC-active may exhibit the complete opposite of WL, *weak antilocalization* (WAL). In this case, the paths of backscattered electrons interfere destructively to yield more delocalized states. This reversal in behavior can be understood to result from the spin DOF becoming an active participant in the Hamiltonian and scattering events. Here, the application of a magnetic field changes the interference of backscattered electrons from destructive to constructive, therefore decreasing the conductivity of a material. The natural signature of SOC-active materials is therefore a negative magneto-conductivity.

The role of localization in graphene, however, is more involved due to the presence of other spin-like DOFs, namely, the sublattice and valley DOFs. In the absence of both SOC and inter-valley scattering (i.e., disorder is smooth on the lattice scale), graphene exhibits a WAL phase, the complete opposite of what is seen in 2DEGs. The manifestation of WAL in this system is a result of graphene's π Berry phase, which precludes electrons from backscattering and thus prevents WL. Another interpretation can be found in considering the pseudospin (sublattice) DOF as an active participant in the Hamiltonian and scattering events, much in a similar manner to how spin becomes an active participant in SOC-active 2DEGs. Upon increasing the concentration of point defects and other short-range scatterers, such that inter-valley scattering no longer remains negligible, the disordered graphene system's localization phase reverses to exhibit a WL phase instead. Likewise, keeping intervalley scattering weak (i.e., intravalley scattering dominates) and instead introducing a strong SOC also pushes graphene from a WAL to a WL phase. Finally, when both disorder and SOC are strong, graphene moves back to WAL behavior (Sousa et al., 2022). Several experiments on graphene-TMD and bilayer graphene-TMD have revealed WAL phases in these systems (Wang et al., 2016; Völkl et al., 2017; Yang et al., 2017; Wakamura et al., 2018; Amann et al., 2022), indicating the presence of strong symmetry-breaking SOC. However, such observations do not provide a direct spectroscopic probe for the size of the various SOC's present. Only recently has the SOC of these systems been accessed directly (Tiwari et al., 2022; Wang et al., 2019).

Spin Hall effect

While SOC might affect the electrical conductivity of graphene-based vdW heterostructures through quantum interference, more profound and exotic behavior can be observed when considering other forms of transport. The SHE is one such example of this, whereby the generation of a pure spin current driven solely by electric fields can be achieved without the need for magnetic fields. In pristine graphene—owing to its negligible intrinsic SOC (Sichau et al., 2019)—the SHE is absent. However, this scenario changes drastically in the presence of disorder-induced SOC (Ferreira et al., 2014; Balakrishnan et al., 2014; Milletari and Ferreira, 2016). Here, the scattering of charge carriers from spin-orbit hot spots aligns spin and orbital angular momentum in opposite directions, resulting in the formation of transverse spin currents; the magnitude of the effect is characterized by the spin Hall angle, γ .

A direct consequence of the SHE in low-dimensional systems is the accumulation of spin at the system's boundaries. Specifically, thin films (2D materials) will accrue a collection of oppositely aligned spins at opposite edges, see Fig. 5, due to the resulting spin current pumping up spins toward one boundary and down spins toward the opposite boundary. In thin wires (1D materials), the spin accumulation can be seen to wind around the wire's surface, much in a similar manner to how a magnetic field appears around a wire carrying an electrical current. Reversing the direction of the applied electrical current reverses the spin accumulation in both cases mentioned here; the up and down spins now accumulate at the opposite boundary to which they had originally found themselves in thin films, and the direction of winding is reversed in thin wires.

Broadly speaking, the SHE arises in two forms: intrinsically and extrinsically. The former of these two is a direct result of the material's band structure, as opposed to being reliant upon external perturbations or extrinsic factors, such as disorder. This manifestation of the SHE can be understood in terms of an internal force experienced by the electrons traveling through the material due to the application of a charge current. This internal force is generated by the SOC experienced by the electrons, and hence is an effect embedded within the band structure of the system. An analogy can be drawn between this spin-orbit force driving the SHE and the Lorentz force responsible for the regular Hall effect. In contrast to the intrinsic SHE is the extrinsic contribution. Here, the generation of a spin current is driven by external mechanisms such as scattering from impurities. In this case, the SHE is the result of asymmetric scattering of electrons based upon their spin; up spins are scattered with a certain directional preference while down spins are scattered with the opposite preference. This type of asymmetric scattering, known as *skew scattering*, plays a central role in graphene-based vdW heterostructures (Milletari et al., 2017).

To illustrate the importance of disorder-induced corrections to transport for these materials, consider the Hamiltonian for graphene with just Rashba coupling (i.e., $\lambda_{sv} = 0$ and neglecting Δ_{KM} , given its small nature in most realistic scenarios). The carrier concentration is typically large enough to place the Fermi energy well above the Rashba pseudogap (i.e., in regime II of the band structure). Assuming only nonmagnetic disorder is present, the system clearly lacks a well-defined quantization axis due to the lack of spin-valley coupling. Therefore, the SHE should not be observable simply because some form of SOC is present. With the inclusion of a spin-valley coupling, it would then be natural to expect the possible occurrence an SHE as a quantization axis will now be well-defined. However, if a theoretical analysis of the SHE for the minimal model without including disorder self-consistently is performed, it would lead one to believe that a finite SHE would exist in the absence of spin-valley coupling. This clearly emphasizes the importance of including disorder in a fully self-consistent manner (Milletari et al., 2017; Milletari and Ferreira, 2016).

Within the Kubo-Streda formalism of linear response (Streda, 1982; Crépieux and Bruno, 2001), the spin Hall conductivity may be written as $\sigma_{yx}^{SH} = \sigma_{yx}^{SH,I} + \sigma_{yx}^{SH,II}$, with (Milletari and Ferreira, 2016; Milletari et al., 2017)

$$\sigma_{yx}^{SH,I} = -\frac{1}{2\pi} \int_{-\infty}^{+\infty} d\omega \frac{df}{d\omega} \left\{ \text{Tr} \left[\mathcal{J}_y^z G_{\omega}^+ \tilde{j}_x G_{\omega}^- \right] - \frac{1}{2} \text{Tr} \left[\mathcal{J}_y^z G_{\omega}^+ \tilde{j}_x G_{\omega}^+ + \mathcal{J}_y^z G_{\omega}^- \tilde{j}_x G_{\omega}^- \right] \right\}, \quad (17a)$$

Fig. 5 Left: Spin textures of spin-majority bands in each valley. The net out-of-plane spin polarization at each valley defines a quantization axis. Right: Spin accumulation at the edges of a thin film due to the SHE. Black arrow: electrical current, orange arrow: spin current, red/blue arrows: up/down spins. The electrons driven by the electrical current are scattered asymmetrically based upon their spin (skew scattering). Here, up spin electrons are scattered preferentially to the left while down spins experience the opposite.

$$\sigma_{yx}^{\text{SH,II}} = \frac{1}{2\pi} \int_{-\infty}^{+\infty} d\omega f(\omega) \text{Re} \left\{ \text{Tr} \left[\mathcal{J}_y^z G_{\omega}^+ \tilde{j}_x \frac{\partial G_{\omega}^+}{\partial \omega} - \mathcal{J}_y^z \frac{\partial G_{\omega}^+}{\partial \omega} \tilde{j}_x G_{\omega}^+ \right] \right\}, \quad (17b)$$

where $\mathcal{J}_y^z$ is the z -polarized spin current operator in the y -direction, $\tilde{j}_x$ is the x component of the disorder-renormalized electric current operator, $G_{\omega}^{\pm}$ are the retarded or advanced disorder-averaged Green's functions for electrons with energy ω , $f(\omega)$ is the Fermi-Dirac distribution, and the trace is over momentum and all internal DOFs (spin, sublattice, and valley). Given the applied electric field, E , generating an electrical current (assumed to be along the x -axis), the resulting spin Hall current can then be determined using $\mathcal{J}_y^{\text{SH}} = \sigma_{yx}^{\text{SH}} E_x$.

The first term, $\sigma_{yx}^{\text{SH,I}}$, is sometimes referred to as the Fermi surface contribution while the second term, $\sigma_{yx}^{\text{SH,II}}$, is similarly called the Fermi sea contribution. In weakly disordered systems, the type II contribution is higher order in the impurity density and hence may be neglected. Similar reasoning applies to the G^+G^+ and G^-G^- terms in the type I contribution. Hence, it turns out that the leading order behavior is dictated solely by the cross term of $\sigma_{yx}^{\text{SH,I}}$. Clearly, the SHE in the metallic regime of disordered materials is essentially a Fermi surface property.

A common representation that helps to visualize how disorder is included into linear response is that of Feynman diagrams. Fig. 6 shows the dominant cross term in diagrammatic form, alongside the Dyson series describing the disorder-averaged Green's functions and the Bethe-Salpeter equation satisfied by the disorder-renormalized vertex. Note, the discussions and analysis here assume that only nonmagnetic (spin-independent) scalar disorder is present. The *dashed lines* represent an electron (*solid line*) scattering from an impurity located at the cross. If $\sigma_{yx}^{\text{SH,I}}$ is evaluated without vertex corrections for the $\lambda_{\text{sv}} = 0$ case, one finds a nonvanishing result in complete contradiction to what is expected. However, including vertex corrections to any order in the number of scattering events, $\sigma_{yx}^{\text{SH,I}}$ can be seen to vanish, thus recovering the expected result for zero spin-valley coupling.

Interestingly, if one were to consider a Fermi energy located within the Rashba pseudogap (regime I of the band structure, $|\varepsilon| < 2|\lambda_{\text{BR}}|$), they would also find a vanishing SHE in the absence of λ_{sv} . However, in this case, the type II contribution would no longer be subleading order and hence also needs accounting for (the cross term of the type I contribution remains the dominant part of $\sigma_{yx}^{\text{SH,I}}$). With this in mind, the computation of Eq. (17) yields (Millettari et al., 2017)

$$\sigma_{yx}^{\text{SH,I}} = \frac{e}{16\pi} \frac{|\varepsilon|}{\lambda_{\text{BR}}} = -\sigma_{yx}^{\text{SH,II}}. \quad (18)$$

Hence, $\sigma_{yx}^{\text{SH}} = 0$ and so the SHE remains absent even in regime I due to the Fermi surface contribution being counteracted by off-surface processes.

Shifting focus to the experimentally relevant situation in which $\lambda_{\text{BR}} \neq 0$ and $\lambda_{\text{sv}} \neq 0$ while the SHE is expected to be observable (due to emergence of an effective spin quantization axis around each valley, see Fig. 5), the role played by disorder changes drastically. If disorder is only accounted for within the Born approximation, where all processes involving three or more scatterings from a single impurity are neglected, then one finds that Eq. (17a) yields a vanishing result. Only upon the inclusion of at least third-order scattering events (at least three scatterings from a single impurity) into the vertex correction does one find a nonzero value for $\sigma_{yx}^{\text{SH,I}}$. By accounting for these higher order processes, a scattering event can now distinguish between left and right based upon the electron's spin along the well-defined quantization axis courtesy of the spin-valley coupling, that is, skew scattering has been included. Therefore, not only are vertex corrections key to understanding the SHE completely, but so too are the higher order scattering mechanisms allowing for the manifestation of the SHE. In other words, the extrinsic SHE due to scalar disorder effects in graphene-based vdW heterostructures is controlled entirely by skew scattering, which is always active provided the existence of a tilted BR-type spin texture at the Fermi level.

As a final note on intrinsic effects, couplings such as electron-phonon and electron-electron interactions, as well as structural defects such as ripples and shears in the individual layers of the heterostructure, are also considered as being intrinsic to the system.

Fig. 6 Diagrammatic representation of the cross term in $\sigma_{yx}^{\text{SH,I}}$ (a), the disorder-average Green's function (b), and vertex correction due to disorder (c). The thick red/blue lines denote retarded/advanced disorder-averaged Green's functions describing electron propagation, thick orange lines can be either retarded/advanced disorder-averaged electron Green's functions but must all be of the same type, thin orange lines indicate the free electron Green's functions, the black circles represent the current and spin current operators (vertices), black crosses represent an impurity, and the orange dashed lines denote an electron scattering from the impurity.

Consequently, the intrinsic SHE can potentially play an important role in clean systems, where electron–phonon coupling dominates at room temperature, or in materials with sharp boundaries between structural domains. Just how major these effects are is still a current area of study; hence they shall not be covered in this article.

Inverse spin galvanic effect

A natural partner to the SHE is the ISGE: the accumulation of spin upon application of an electric field without an associated spin current. Unlike the SHE, this spin accumulation manifests throughout the whole system. Rather, a nontrivial spin texture, facilitated by the interfacial breaking of inversion symmetry, is enough to allow for a nonzero spin polarization when an electrical current is passed through the system. To demonstrate this, consider, once again, the minimal Dirac–Rashba Hamiltonian (only $\lambda_{\text{BR}} \neq 0$). It was shown above that the electron spins are locked in-plane and perpendicular to the electron momentum. In the absence of an electric field (i.e., in equilibrium), the Fermi rings forming the Fermi surface (two in regime II and Ia and one in regime Ib) are perfect circles around each Dirac point. Consequently, the electrons forming these rings yield a net spin polarization of zero (as expected of the nonmagnetic materials discussed here). However, when an electric field is introduced, these Fermi rings are shifted such that they are no longer rotationally symmetric about their respective Dirac points, see Fig. 7. Therefore, the sum of the electron spins from each Fermi ring yields a nonzero spin polarization.

The direction of the resulting spin polarization is entirely dependent upon the system’s spin texture. In the case of the Dirac–Rashba model above, the ISGE yields a spin polarization that is perpendicular to the applied electric field. The inclusion of a spin–valley coupling does not change the resulting spin polarization compared to the Dirac–Rashba model (the Onsager-reciprocal phenomena, namely, the SHE and ISGE, were measured in Camosi et al., 2022). This is due to the out-of-plane component gained by the electron spins being opposite in sign between valleys (i.e., $\pm$ in the $K_{\pm}$ valleys). Hence, summing over the contribution from both valleys, one finds a vanishing z component of spin accumulation. The role of the Kane–Mele-type SOC in these systems is negligible and hence does not contribute any meaningful changes to the spin texture either.

An alternative method to manipulating the spin texture of these materials has been found through the introduction of a twist between a graphene monolayer and a TMD monolayer (Li and Koshino, 2019; David et al., 2019; Péterfalvi et al., 2022; Veneri et al., 2022). By introducing a rotational off-set between the two layers, both the Rashba and spin–valley couplings are affected and acquire a twist-angle, θ , dependence. Not only are the magnitudes of these SOC’s changed by twisting, but so too is the form of the Rashba term in the Hamiltonian. Upon the introduction of twisting, the spin–valley term maintains the same form as in Eq. (12) but with λ_{sv} replaced by $\tilde{\lambda}_{\text{sv}}(\theta)$ ($\tilde{\lambda}_{\text{sv}}(0) = \lambda_{\text{sv}}$), and the Rashba term becomes

$$H_{\text{R}}(\theta) = \tilde{\lambda}_{\text{BR}}(\theta) e^{i s_z \alpha_{\text{R}}(\theta)/2} (\sigma_x s_y - \sigma_y s_x) e^{-i s_z \alpha_{\text{R}}(\theta)/2}, \quad (19)$$

where $\tilde{\lambda}_{\text{BR}}(0) = \lambda_{\text{BR}}$, and $\alpha_{\text{R}}(\theta)$ is known as the *Rashba phase*. The exact way in which the Rashba coupling, spin–valley coupling, and Rashba phase vary with twist-angle depends heavily upon the material that graphene is paired with. A guaranteed property, however, is that $\alpha_{\text{R}}(\theta) = c_1 \pi$ for $\theta = c_2 \pi/6$ for $c_1, c_2 \in \mathbb{Z}$. In any case, the spin texture will clearly be affected by the change in the Rashba coupling term’s form. In fact, as the layers are twisted relative to one another, the electron spins can be seen to also rotate away from being locked perpendicular to their momenta. This rotation of the spin texture can be seen in Fig. 8, where the out-of-plane component due to spin–valley coupling has been neglected for ease of illustration. It turns out that, for some materials, there exists a critical angle, θ_c , where the spin texture is entirely radial (Fig. 8c), sometimes referred to as a *Weyl-type* or *hedgehog* spin texture. Clearly, by being the perpendicular analog of the untwisted case, the resulting spin polarization will be perfectly collinear to the applied electric field. For any twist-angles away from $\theta = 0, \pm \theta_c, \pi/6$, the net spin polarization will be in-plane but neither perpendicular nor collinear to an applied electrical current. The value of θ_c is sensitive to the partner TMD used, atomic registry, strain distribution, and external perturbations (e.g., perpendicular electric field, Naimer et al., 2021), and hence will vary significantly between materials. Consequently, meaningful predictions for θ_c are challenging to make. For example, graphene-WSe₂

Fig. 7 The manifestation of a nonequilibrium spin polarization with the application of an electric field is pictured above for a system with only Rashba SOC. Focus is placed on a single Fermi ring for ease of illustration. Left: Fermi ring for a system with zero current. The sum of electron spins (orange arrows) yields zero by symmetry. Right: an applied electric field shifts the Fermi ring from its original position (gray), with the electron spins on the Fermi surface rotating to maintain the spin–momentum locking typical of Rashba SOC, resulting in a nonzero spin polarization (red arrow). By inspection, all spins, except those on the x -axis, can be seen to rotate toward alignment with the y -axis. As a result, the net spin polarization is parallel to the y -axis in this case.

Fig. 8 Introduction of a twist between the layers of a graphene-TMD vdW heterostructure can be seen to rotate the spin texture of the Fermi rings. (a) $\theta = 0$, all spin are locked in-plane and perpendicular to the momentum. (b) At arbitrary twist angles, $\theta \neq c_2\pi/6, \theta_c$, the electron spin are still fixed in-plane but not perpendicular of (anti-)parallel to the electron momentum. (c) At critical twist angles, $\theta = \theta_c$, the electron spins (anti-)align with their momentum.

has been predicted to host a $\theta_c \approx 14^\circ$ (this prediction is based on an 11-band tight-binding model of the twisted heterostructures informed by both density functional theory calculations (Fang et al., 2015; Gmitra et al., 2016) and available angle-resolved photoemission data (Pierucci et al., 2016; Nakamura et al., 2020). In contrast, even the existence of a critical twist angle for graphene-MoS₂ is difficult to ascertain given the variation in the reported material parameters of theory and experiment (Péterfalvi et al., 2022).

Defects and structural disorder are also expected to play a significant role. Of particular relevance is *twist-angle disorder*, a type of spatial inhomogeneity that is ubiquitous in realistic systems (Uri et al., 2020). Its impact on transport properties is expected to depend crucially on the comparative sizes of the spin diffusion length, l_s , and the twist-puddle size, ξ (i.e., typical size of regions with a similar twist-angle). When $l_s \ll \xi$, the twist-angle disorder can be considered smooth and hence can be incorporated into linear-response calculations through an appropriate averaging procedure (e.g., a Gaussian or box weighting could be applied, Veneri et al., 2022). Though it is challenging to make first-principles predictions about the twist-angle behavior of the Rashba phase for realistic systems, the dependence of coupled spin-charge transport phenomena on the Rashba phase can be reliably studied by replacing the standard Rashba SOC in the low-energy Hamiltonian of Eq. (12) with Eq. (19). In this case, the point group symmetry of the system, and therefore Hamiltonian, is once more reduced, going from C_{3v} to C_3 for nontrivial twist angles.

To understand this from a quantitative perspective, one notes that the ISGE can be written mathematically as $S_x = K_{x\beta} E_\beta$ (assuming Einstein summation), where $K_{x\beta}$ are the elements of the *spin susceptibility* tensor. As in the SHE, the spin susceptibility tensor can be determined using linear response theory (Milletari and Ferreira, 2016; Milletari et al., 2017), $K_{x\beta} = K_{x\beta}^I + K_{x\beta}^{II}$,

$$K_{x\beta}^I = -\frac{1}{4\pi} \int_{-\infty}^{+\infty} d\omega \frac{df}{d\omega} \left\{ \text{Tr} [s_x G_\omega^+ \tilde{j}_x G_\omega^-] - \frac{1}{2} \text{Tr} [s_x G_\omega^+ \tilde{j}_x G_\omega^+ + s_x G_\omega^- \tilde{j}_x G_\omega^-] \right\}, \quad (20a)$$

$$K_{x\beta}^{II} = \frac{1}{4\pi} \int_{-\infty}^{+\infty} d\omega f(\omega) \text{Re} \left\{ \text{Tr} \left[s_x G_\omega^+ \tilde{j}_\beta \frac{\partial G_\omega^+}{\partial \omega} - s_x \frac{\partial G_\omega^+}{\partial \omega} \tilde{j}_x G_\omega^+ \right] \right\}, \quad (20b)$$

where the Green's functions now contain the twisted form of the Rashba Hamiltonian. For disordered materials the G^+G^+ and G^-G^- of the type I contribution, as well as the type II contribution, can once again be neglected. Consequently, the results for the in-plane components of the twisted spin susceptibility tensor can be related back to the untwisted ISGE, albeit with modified Rashba and spin-valley couplings,

$$\begin{aligned} K_{xx}(\tilde{\lambda}_{BR}(\theta), \tilde{\lambda}_{sv}(\theta); \theta) &= K_{yx}(\tilde{\lambda}_{BR}(\theta), \tilde{\lambda}_{sv}(\theta); 0) \sin \alpha_R(\theta), \\ K_{yx}(\tilde{\lambda}_{BR}(\theta), \tilde{\lambda}_{sv}(\theta); \theta) &= K_{yx}(\tilde{\lambda}_{BR}(\theta), \tilde{\lambda}_{sv}(\theta); 0) \cos \alpha_R(\theta), \end{aligned} \quad (21)$$

$$K_{yx}(\tilde{\lambda}_{BR}, \tilde{\lambda}_{sv}; 0) = \frac{4ev\epsilon}{\pi n u_0^2 \epsilon^4 (\tilde{\lambda}_{BR}^2 + \tilde{\lambda}_{sv}^2) - \epsilon^2 \tilde{\lambda}_{sv}^4 + 3\tilde{\lambda}_{BR}^2 \tilde{\lambda}_{sv}^4}, \quad (22)$$

where n is the impurity concentration and u_0 is the strength of the scalar impurities. These results are strictly valid for perfectly aligned heterostructures. For systems with smooth twist-disorder landscapes ($l_s \ll \xi$), an intuitive approximate result can be obtained by taking the convolution of Eq. (21) with a suitable twist-disorder distribution function (Veneri et al., 2022). For twist

angles $\theta \neq \theta_c$, $c_2\pi/6$, both in-plane components of the spin susceptibility tensor will be nonvanishing, thus yielding a nontrivial polarization ($S_x, S_y \neq 0$). At the critical twist angle, the Rashba phase must vanish ($\alpha_R(\theta_c) = 0$), and hence a *collinear Edelstein effect* (CEE) can be achieved, whereby the resulting spin polarization will be purely (anti-)parallel to the applied electrical current (c.f. Fig. 8c). What makes these twisted graphene-TMD vdW heterostructures appealing is the ease with which the SOC and spin texture can be manipulated; only a simple twist is needed to adjust them. This sets these systems apart from 2DEGs, where both Rashba-type and Dresselhaus-type SOC are required (Trushin and Schliemann, 2007). Control of these SOC in 2DEGs is achieved via asymmetric doping and the tuning of quantum well widths (Ganichev and Golub, 2014), a set of processes far more complicated and involved than simple twisting. For further details, the reader is referred to Veneri et al. (2022) where the CEE phenomenon was predicted.

Observing spin–charge interconversion

To make use of graphene's large l_s while also studying the effects of proximity-induced SOC, spin-valve setups are typically used to measure the ISHE and SGE (the inverse SHE and spin galvanic effect, respectively). In this case, rather than trying to measure a spin current using an FM contact, an electrical current is measured instead by converting an injected spin current into an electrical current (Valenzuela, 2009). A schematic of a spin-valve experiment is shown in Fig. 9.

Spin valves operate by using a single FM contact to inject a spin current into graphene. This spin current is then able to flow along the isolated graphene channel until it reaches a T-junction, where it enters a region of high SOC. This region is no longer characterized by just monolayer graphene; instead, it now contains graphene layered on top of a TMD. As a result, the spin current entering this region undergoes the ISHE (due to any out-of-plane spin components) and generates an electrical current perpendicular to the injected spin current. Likewise, the electrons entering the high SOC region naturally also have a component of in-plane spin polarization and so are subject to the SGE, which also generates a perpendicular electrical current. Specifically, the component of the electron's spin parallel to the spin current generates an electrical current via the SGE while the component of spin in-plane and perpendicular to the spin current yields an electrical current via the collinear SGE (if the material permits this process). The ensuing nonlocal resistance measured across the T-junction is therefore characterized by the spin–charge interconversion effects at the heart of modern spintronics.

In order to distinguish between the different electrical signals arising from the ISHE, SGE, and collinear SGE, a combination of magnetic fields must be used in conjunction with various FM orientations. The effect of applying a magnetic field to this setup is to cause spin precession about the applied field. The strength of the measured resistance in the T-junction will then depend on the magnetic field strength (how quickly the spins precess), and the length of the graphene channel (how long the spins have to precess). By combining the spin-valve measurements for various magnetic fields and FM orientations, the electrical signals associated to each of the aforementioned proximity-induced ISHE, and SGE can be isolated by means of a simple symmetry analysis (Cavill et al., 2020). A set of recent spin-valve experiments have revealed graphene-TMD heterostructures to yield room-temperature nonlocal resistances of order 1–10 m Ω due to the ISHE and SGE (Safeer et al., 2019a; Ghiasi et al., 2019; Benítez et al., 2020). Alternatively, the Onsager-reciprocal phenomena, namely, the SHE and ISGE, can be discerned by measuring the spin accumulation in the direction of the spin current at opposite sides of the high SOC region, as was done in the experiment of Camosi et al. (2022). The latter approach requires a complex multiterminal architecture but has the advantage that it permits isolation of the SHE and ISGE in situations for which the TMD is conducting and thus directly influences the spin–charge conversion processes (due to its high intrinsic SOC).

Additionally, spin-valve measurements allow us to distinguish between conventional and anisotropic spin-charge conversion processes. An anisotropic SGE has been recently observed in graphene proximity-coupled to semimetallic (low-symmetry) TMDs (Safeer et al., 2019b). Likewise, an anisotropic ISGE characterized by the presence of spin polarization components parallel and orthogonal to the driving current has been reported experimentally in Camosi et al. (2022). However, an experimental demonstration exploiting twist-angle control in a graphene-semiconducting TMD heterostructures as described by Eq. (21) has yet to be achieved.

Fig. 9 Graphene-based spin valve setup. An electrical current, I , passed through a ferromagnetic contact (blue box) injects a spin current into a graphene sheet. This spin current then travels along a graphene channel and into a region of enhanced SOC (dashed red region), due to proximity with a TMD (red box). This generates a charge accumulation in the arms of the T-junction due to the ISHE and SGE, which yields a nonlocal voltage in the steady state, V_{nl} , across the bar under the open circuit conditions.

While spin-valve setups are ideally suited for studies of spin dynamics and spin–charge interconversion processes, they do not allow one to discern the size of the SOC present in a graphene-on-TMD heterostructure. To do this, measurement of the Shubnikov–de Haas (SdH) oscillations must be made. The reconstruction of the low-energy electronic structure from SdH data allows for the determination of the average SOC, $\bar{\lambda} = \sqrt{\lambda_{\text{BR}}^2 + \lambda_{\text{sv}}^2}$ (Tiwari et al., 2022). Experiments have revealed that the typical SOC present in these materials is $\bar{\lambda} \simeq 2.51$ meV. This average value is in accord to the predictions of microscopic theories for vdW heterostructures (Milletari et al., 2017; Offidani et al., 2017) regarding the observation of significant spin–charge interconversion efficiencies at room temperature, and is indeed compatible with the spin-valve measurements (Safeer et al., 2019a; Ghiasi et al., 2019; Benítez et al., 2020; Camosi et al., 2022; Li et al., 2020; Hoque et al., 2021), thus demonstrating that proximity-induced SOC is responsible for the observed nonlocal resistances.

Conclusion

This article has presented the role of graphene in modern spintronic devices, with a specific emphasis on how its partnership with other 2D materials can allow for bespoke systems with desirable electronic and spin transport properties. By constructing a low-energy theory of graphene, it becomes clear that transport phenomena in graphene-based systems will be dominated by the behavior of electrons around the Dirac points. From a physical point of view, one of the most striking features of isolated graphene is the description of its electrons as massless chiral Dirac fermions. Furthermore, the decoherence of spins in graphene occurs over large distances, allowing for long-range spin transport, a direct result of the extremely weak intrinsic SOC (Kane–Mele) appearing naturally in graphene. However, despite its ability to host long-range spin diffusion, graphene does not have a natural mechanism allowing for distinct spin control. This can ideally be achieved by pairing it with other materials that enhance its SOC.

In particular, the use of TMDs proximity-coupled to graphene gives rise to significant SOC, of the order of meV, which allows meaningful spin currents and nonequilibrium spin polarizations, via the SHE and ISGE, respectively, to manifest in the graphene layer. Consequently, electronic control of spin transport can be easily achieved and hence amalgamates well with current technological architectures. One major focus of spintronics is the implementation of the SHE and ISGE to generate large spin accumulations and polarizations that can be used to change the magnetization of a ferromagnet. In this case, the magnetization experiences a torque due to the SOC-related phenomena and so is referred to as a *spin-orbit torque* (SOT). The use of SOTs in technology could allow for the realization of SOT-based magnetic random access memory (SOT-MRAM), removing our reliance upon volatile memory and thus reducing energy consumption. This route away from traditional RAM appears to bear much promise and remains as a current area of interest in research with many facets and subtleties still requiring further study.

As a final note, while not covered in this article, interface-induced magnetic exchange interaction is also becoming increasingly important in the field (e.g., as means to allow the manifestation of quantum anomalous Hall phases and spin-dependent Seebeck effect in graphene (Offidani and Ferreira, 2018; Ghiasi et al., 2021)), and the reader is referred to the literature for further details. The same goes for high-temperature topologically nontrivial phases of matter—exhibiting technologically relevant phenomena like the quantum spin Hall effect (Wu et al., 2018)—and the discovery of 2D vdW magnets (Lee et al., 2016; Gong et al., 2017; Huang et al., 2017), which are likely to open up interesting avenues across many emergent fields, including topological quantum computation, spin-orbitronics, magnonics, and antiferromagnetic spintronics (Freedman et al., 2003; Dolui et al., 2020; Xing et al., 2019; Xiao and Tong, 2022).

Abstract

This brief review presents the historical background together with the theoretical and experimental results on optical spin orientation in semiconductors obtained during half a century of intense studies. Absorption of a circularly polarized photon results in the creation of an electron-hole pair with the total spin equal to the angular momentum of the photon. The degree of circular polarization of the recombination radiation serves as a useful and sensitive indicator of the carriers' spin state and its changes under the influence of external factors and relaxation processes. Physical phenomena observed with spin-polarized electrons are briefly reviewed.

Key points

- Historical background: spin physics
- Description of the phenomenon of optical orientation
- Relevant spin-dependent interactions in semiconductors
- Role of the spin in optical phenomena
- Description of spin relaxation
- Role of spin in transport phenomena

Introduction: Historical background

Maybe the first step toward today's activity was made nearly a century ago by Robert Wood when even the notion of electron spin was not yet introduced. In a charming paper, Wood and Ellett (1924) describe how the initially observed high degree of polarization of mercury vapor fluorescence (resonantly excited by polarized light) was unexpectedly found to diminish significantly in later experiments. "It was then observed that the apparatus was oriented in a different direction from that which obtained in earlier work, and on turning the table on which everything was mounted through ninety degrees, bringing the observation direction East and West, we at once obtained a much higher value of the polarization."

In this way Wood and Ellett discovered what we now know as the Hanle effect, i.e. depolarization of luminescence by transverse magnetic field (the Earth's field in their case). It was Hanle (1924) who carried out detailed studies of this phenomenon and provided the physical interpretation.

The subject did not receive much attention until 1949 when Brossel and Kastler (1949) initiated profound studies of optical pumping in atoms. (See Kastler's Nobel Prize award lecture, 1967.) The basic physical ideas and the experimental technique of today's research originate from these seminal papers: creation of a non-equilibrium distribution of atomic angular momenta by optical excitation, manipulating this distribution by applying *dc* or *ac* fields, and detecting the result by studying the luminescence polarization.

The relaxation times for the decay of atomic angular momenta can be quite long, especially when hyperfine splitting due to the nuclear spin is involved. A number of important applications have emerged from these studies, such as gyroscopes and hypersensitive magnetometers. The detailed understanding of various atomic processes and of many aspects of interaction between light and matter was pertinent to the future developments, e.g. for laser physics.

The first experiment on optical spin orientation of electrons in a *semiconductor* (Si) was done by Lampel (1968), as a direct application of the ideas of optical pumping in atomic physics. The great difference, which has important consequences, is that now those are the free conduction band electrons (or holes) that get spin-polarized, rather than electrons bound in an atom. This pioneering work was followed by experimental and theoretical studies mostly performed by small research groups at Ioffe Institute in St. Petersburg (Leningrad) and at Ecole Polytechnique in Paris in the 1970s and early 1980s.

At the time, this research met with almost total indifference by the rest of the physics community, and the entire world population of researchers in the field never exceeded 20 persons. Now it can be counted by the hundreds and the number of publications by the thousands. The entire field is reviewed in the "Spin Physics in Semiconductors" book (Dyakonov, 2017).

Overview of the subject

In the process of interband absorption of a photon in a semiconductor, an electron in the conduction band and a hole in the valence band are generated, the total spin of the electron and the hole being equal to the angular momentum of the photon absorbed. Photons of right or left circularly polarized light have a projection of the angular momentum on the direction of the wave vector equal to $+1$ or -1 , respectively (in units of the Planck constant $\hbar$). This angular momentum is distributed between the photoexcited electron and hole according to the selection rules determined by the band structure of the semiconductor.

The photoexcited electrons and hole live some time τ before recombination. During this time the spin orientation of carriers decreases due to various relaxation processes. If the orientation has not entirely disappeared by the time of recombination, the recombination radiation will be partially circularly polarized. Thus the process of optical orientation includes two stages: creation of spin-oriented carriers in absorption of circularly polarized light, and spin relaxation during the carriers' lifetime. The degree of circular polarization of the recombination radiation serves as a useful and sensitive indicator of the carriers' spin state and its changes under the influence of external factors and relaxation processes determining the kinetics of the nonequilibrium carriers in a semiconductor.

Along with the optical one, other methods of detection of the carriers' spin orientation are possible. Thus in the experiments of Lampel (1968) nuclear magnetic resonance was used as a detection method. The ^{29}Si nuclei in a silicon crystal were polarized due to their hyperfine interaction with optically oriented electrons.

Optical detection was first used by Parsons (1969) in his studies of optical spin orientation in GaSb, see also Parsons (1971). A typical experiment on optical orientation is schematically presented in Fig. 1. The degree of spin orientation of photoexcited carriers is determined by the details of the band structure, the type of optical transition, the relaxation processes, as well as by the influence of various external factors. This is why optical orientation is an effective method of studying a number of physical processes in semiconductors.

In the most detailed way optical orientation was studied in GaAs and (GaAl)As solid solutions. The first experiments on optical orientation in these materials were performed by Ekimov and Safarov (1970) and by Zakharchenya et al. (1971). Optical orientation reveals itself in all types of edge luminescence, in particular in recombination radiation of optically oriented excitons. Exciton orientation was discovered in hexagonal crystals of CdSe by Gross et al. (1971). Measurements of the polarization of hot luminescence allow to study the energy and momentum relaxation of hot electrons.

A quite special kind of phenomena involves optical effects due to dynamic polarization of the lattice nuclei of a semiconductor. The nuclei, polarized by optically oriented electrons, via *hyperfine interaction* create an effective magnetic field which, in turn, acts on

Fig. 1 Schematic drawing of a typical experiment on optical spin orientation. A circularly polarized beam of light (1) induces interband transitions in a semiconductor (2). The degree of circular polarization of the recombination radiation (3) is measured.

the electron spins and thereby on the circular polarization of the luminescence. Studies of associated phenomena began since the work of [Ekimov and Safarov \(1972\)](#) who detected nuclear magnetic resonance (NMR) for the lattice nuclei of a (GaAl)As solid solution by resonant changes in the degree of circular polarization of luminescence.

Below the basic theoretical ideas related to optical orientation of electrons and nuclei in semiconductors, as well as the main experimental results, are reviewed. Although most of the considerations are quite general, we shall, for definitiveness, consider semiconductors with the band structure of GaAs, for which processes accompanying optical orientation are best studied experimentally.

Band structure of gallium arsenide

Most of the experimental work on optical spin orientation was conducted with GaAs crystals and GaAlAs solid solutions. The band structure of GaAs, a typical zinc-blend semiconductor, is schematically presented in [Fig. 2](#). Near the center of the Brillouin zone there is a simple isotropic conduction band, which is doubly degenerate in spin. The valence band, consists of the sub-bands of light (*lh*) and heavy (*hh*) holes which are anisotropic, and the isotropic split-off band (*so*), all doubly degenerate.

Spin interactions

Here we enumerate the possible types of spin interactions that can be encountered in a semiconductor. The existence of an electron spin, $s = 1/2$, and the associated magnetic moment of the electron, $\mu = eh/2mc$, has many consequences, some of which are very important and define the very structure of our physical world, while others are subtler, but still quite interesting. Below is a list of these consequences in the order of decreasing importance.

The Pauli principle

Because of $s = 1/2$, the electrons are fermions, and so no more than one electron per quantum state is allowed. Together with Coulomb law and Schrödinger equation, it is this principle that is responsible for the structure of atoms, chemical properties, and the physics of condensed matter, biology included. It is interesting to speculate what would our world look like without the Pauli

Fig. 2 Band structure of GaAs: *c* – conduction band, *hh* – heavy hole band, *lh* – light hole band, *so* – split-off band.

principle and whether any kind of life would be possible in such a world. Probably, only the properties of the high-temperature, fully ionized plasma would remain unchanged!

Note that the Pauli exclusion principle is not related to any interaction: if we could switch off the Coulomb repulsion between electrons (but leave intact their attraction to the nuclei), no serious changes in atomic physics would occur, although some revision of the Periodic Table would be needed. Other manifestations of the electronic spin are due to interactions, either electric (the Coulomb law) or magnetic (related to the electron magnetic moment μ).

Exchange interaction

It is, in fact, the result of the electrostatic Coulomb interaction between electrons, which becomes spin-dependent because of the requirement that the wavefunction of a pair of electrons be anti-symmetric with respect to the interchange of electron coordinates and spins. If the electron spins are parallel, the coordinate part of the wavefunction should be *antisymmetric*: $\psi_{\uparrow\uparrow}(\mathbf{r}_2, \mathbf{r}_1) = -\psi_{\uparrow\uparrow}(\mathbf{r}_1, \mathbf{r}_2)$, which means that the probability that two electrons are very close to each other ($\mathbf{r}_1 = \mathbf{r}_2$) is small compared to the opposite case, when the spins are antiparallel and accordingly their coordinate wavefunction is *symmetric*. Electrons with parallel spins are then better separated in space, so that their repulsion is less and consequently the energy of electrostatic interaction for parallel spins is lower. This *exchange interaction* is responsible for ferromagnetism. In semiconductors, it is normally not of major importance, except for magnetic semiconductors (like CdMnTe) and for the semiconductor-ferromagnet interfaces.

Spin-orbit interaction

If an observer moves with a velocity $\mathbf{v}$ in an external electric field $\mathbf{E}$, he will see a magnetic field $\mathbf{B} = (1/c)\mathbf{E} \times \mathbf{v}$, where c is the velocity of light. This magnetic field acts on the electron magnetic moment. This is the physical origin of the spin-orbit interaction, the role of which strongly increases for heavy atoms (with large Z). The reason is that there is a certain probability for the outer s -electron to approach the nucleus and thus to see the very strong electric field produced by the unscreened nuclear charge $+Ze$ at the center. Due to spin-orbit interaction, any electric field acts on the spin of a moving electron.

Being perpendicular both to $\mathbf{E}$ and $\mathbf{v}$, in an atom the vector $\mathbf{B}$ is normal to the plane of the orbit, thus it is parallel to the orbital angular momentum $\mathbf{L}$. The energy of the electron magnetic moment in this magnetic field is $\pm \mu B$ depending on the orientation of the electron spin (and its magnetic moment) with respect to $\mathbf{B}$ (or to $\mathbf{L}$). Thus the spin-orbit interaction can be written as $A\mathbf{L} \cdot \mathbf{S}$, the constant A depending on the electron state in an atom. This interaction results in a splitting of atomic levels (the *fine structure*), which strongly increases for heavy atoms.

In semiconductors, the spin-orbit interaction depends not only on the velocity of the electron (or its quasi-momentum), but also on the structure of the Bloch functions defining the motion on the atomic scale. Like in isolated atoms, it defines the values of the electron g -factors. Spin-orbit interaction is key to our subject as it enables optical spin orientation and detection (the electrical field of the light wave does not interact directly with the electron spin). It is (in most cases) responsible for spin relaxation. And finally, it makes the transport and spin phenomena interdependent.

Hyperfine interaction with nuclear spins

This is the magnetic interaction between the electron and nuclear spins, which may be quite important if the lattice nuclei in a semiconductor have non-zero spin (like in GaAs). If the nuclei get polarized, this interaction is equivalent to the existence of an effective nuclear magnetic field acting on electron spins. The effective field of 100% polarized nuclei in GaAs would be several Tesla! Because the nuclear magnetic moment is so small (~ 2000 times less than that of the electron) the equilibrium nuclear polarization at the very high magnetic field of 100 T and a temperature of 1 K would be only about 1%. However, much higher degrees of polarization may be easily achieved through *dynamic nuclear polarization* due to hyperfine interaction with non-equilibrium electrons. Experimentally, non-equilibrium nuclear polarization of several percent is easily achieved. Similar to the spin-orbit interaction, the hyperfine interaction may be expressed in the form $A\mathbf{I} \cdot \mathbf{S}$ (the Fermi contact interaction), where $\mathbf{I}$ is the nuclear spin, $\mathbf{S}$ is the electron spin, and the hyperfine constant A is proportional to $|\psi(0)|^2$, the square of the electron wave function at the location of the nucleus.

Like spin-orbit interaction, the hyperfine interaction strongly increases in atoms with large Z , and for the same reason. An s -electron in an outer shell has a certain probability to be at the center of the atom, where the nucleus is located, and the nearer it is to the center, the less is the nucleus shielded by the inner electrons. Thus the electron wavefunction of an s -electron will have a sharp spike in the vicinity of the nucleus. For example, for the In atom the value of $|\psi(0)|^2$ is 6000 times larger than in the Hydrogen atom! For p -states (angular momentum $l = 1$), and generally for states with $l \neq 0$, the Fermi interaction does not work, since $\psi(0) = 0$, and the electron and nuclear spins are coupled by the much weaker dipole-dipole interaction.

The dynamic nuclear polarization under conditions of optical orientation of electrons is in fact a result of deep *cooling* of the nuclear spin system. Convincing experimental proof of such an interpretation was obtained by [Fleisher et al. \(1976\)](#) Optically oriented electrons and polarized lattice nuclei form a strongly coupled system. High sensitivity to small external magnetic fields, long relaxation times and typical nonlinear effects (hysteresis, self-sustained oscillations) are characteristic of this system.

Magnetic interaction

This is the direct dipole-dipole interaction between the magnetic moments of a pair of electrons. For two electrons located at neighboring sites in a crystal lattice this gives energy on the order of 1 K. This interaction is normally too weak to be of any importance in semiconductors.

Photo-generation of carriers and luminescence

In the process of interband absorption of a photon with energy $\hbar\omega > E_g$ in a semiconductor, an electron in the conduction band and a hole in the valence band are generated. During the process the (quasi)momentum is conserved, however the photon momentum $\hbar k = 2\pi\hbar/\lambda$, where λ is the photon wavelength, is very small (compared, to the electron thermal momentum) and normally may be neglected. In this approximation the optical transitions are *vertical*: to see what happens, we must simply apply a vertical arrow of length $\hbar\omega$ to Fig. 1, so that the arrow touches one of the valence bands and the conduction band. The ends of the arrow will give us the initial energies of the generated electrons and holes. An electron may be created in company with heavy hole, or a light hole; for $\hbar\omega > E_g + \Delta$ the electron-hole pair can also involve a hole in the split-off band.

Note, that for a given photon energy the initial electron energy will be different for those three processes. The photoexcited carriers live some time τ before recombination, which may be radiative (i.e. accompanied by photon emission, which results in luminescence), or non-radiative. In direct-band semiconductors, like GaAs, the recombination is predominantly radiative with a lifetime on the order of 1 ns. It is important to realize that this time is normally *very long* compared to the carriers' thermalization time. Thermalization means energy relaxation of carriers in their respective bands due to phonon emission and absorption, which results in an equilibrium Boltzmann (or Fermi, depending on temperature and concentration) distribution function of electrons and holes. Thermal equilibrium *between electrons and holes* is established by recombination, on the time scale τ .

Because the recombination time τ is so long compared to the energy relaxation time, the luminescence is produced mostly by *thermalized* carriers and the emitted photons have energies close to the value of E_g , irrespective of the energy of exciting photons.¹ It should be noted that semiconductors are normally either intentionally, or non-intentionally doped by impurities. In a *p*-type semiconductor at moderate excitation power the number of photo-generated holes is small compared to the number of equilibrium holes, so that the photo-created electron will recombine with these equilibrium holes, rather than with photo-generated ones.

Angular momentum conservation in optical transitions

Along with energy and momentum conservation, the conservation of the angular momentum is a fundamental law of Physics. Just like particles, electromagnetic waves have angular momentum. Photons of right or left polarized light have a projection of the angular momentum on the direction of their propagation (helicity) equal to $+1$ or -1 , respectively (in units of $\hbar$). Linearly polarized photons are in a superposition of these two states.

When a circularly polarized photon is absorbed, this angular momentum is distributed between the photoexcited electron and hole according to the selection rules determined by the band structure of the semiconductor. Because of the complex nature of the valence band, this distribution depends on the value of the momentum of the created electron-hole pair ($\mathbf{p}$ and $-\mathbf{p}$). However, it can be shown that if we take the average over the directions of $\mathbf{p}$, the result is the same as in optical transitions between atomic states with $j = 3/2$, $m_j = -3/2, -1/2, +1/2, +3/2$ (corresponding to bands of light and heavy holes) and $j = 1/2$, $m_j = -1/2, +1/2$ (corresponding to the conduction band).

Possible transitions between these states, as well as between states in the split-off band and the conduction band, for absorption of a right circularly polarized photon with corresponding relative probabilities are presented in Fig. 3.

Note, that if we add up all transitions, which is the correct thing to do if the photon energy sufficiently exceeds $E_g + \Delta$ the two spin states in the conduction band will be populated equally. This demonstrates the role of spin-orbit interaction for optical spin pumping.

Optical spin orientation and detection

To date, the most efficient way of creating non-equilibrium spin orientation in a semiconductor is provided by interband absorption of circularly polarized light. It can be seen from Fig. 2 that for $E_g < \hbar\omega < E_g + \Delta$ this absorption produces an average electron spin along the direction of excitation equal to $(-1/2)(3/4) + (+1/2)(1/4) = -1/4$ and an average hole spin equal to $+5/4$, with a sum $+1$, equal to the angular momentum of the absorbed right circularly polarized photon. Thus in a *p*-type semiconductor the degree of spin polarization of the photo-excited electrons will be -50% , the minus sign indicating that the spin orientation is opposite to the direction of the angular momentum of incident photons.

¹A small part of the excited electrons can emit photons before losing their energy by thermalization. The studies of the spectrum and polarization properties of this so-called *hot luminescence* reveal interesting and unusual physics, (Dymnikov, 1976; Mirlin, 1984).

Fig. 3 Optical transitions between levels with $j = 3/2$ and $j = 1/2$ (the bands of light and heavy holes, and the split-off band) and the levels with $j = 1/2$ (the conduction band) during an absorption of a right-polarized photon. The probability ratio for the three transitions can be calculated to be 3:2:1.

If our electron immediately recombines with its partner hole, a 100% circularly polarized photon will be emitted. However in a p -type semiconductor electrons will predominantly recombine with the majority holes, which are not polarized. Then the same selection rules show that the circular polarization of luminescence should be $P_0 = 25\%$, if the holes are not polarized, and if no electron spin relaxation occurs during the electron lifetime τ , i.e. if $\tau_s \gg \tau$, where τ_s is the electron spin relaxation time. Generally, the degree P of circular polarization of the luminescence excited by circularly polarized light is less than P_0 :

$$P = P_0 \left(1 + \frac{\tau}{\tau_s} \right) \quad (1)$$

In an optical spin orientation experiment a semiconductor (usually p -type) is excited by circularly polarized light with $\hbar\omega > E_g$. The circular polarization of the luminescence is analyzed, which gives a direct measure of the electron spin polarization. Actually, the degree of circular polarization is simply equal to the average electron spin. Thus various spin interactions can be studied by simple experimental means. The electron spin polarization will be measured provided the spin relaxation time τ_s is not very short compared to the recombination time τ , a condition, which often can be achieved even at room temperature.

Spin relaxation

Spin relaxation, i.e. disappearance of initial non-equilibrium spin polarization, is the central issue for all spin phenomena. Spin relaxation can be generally understood as a result of the action of fluctuating in time magnetic fields. In most cases, these are not real magnetic fields, but rather “effective” magnetic fields originating from the spin-orbit, or, sometimes, exchange interactions.

Generalities

A randomly fluctuating magnetic field is characterized by two important parameters: its amplitude and its correlation time, τ_c , i.e. the time during which the field may be roughly considered as constant. Instead of the amplitude, it is convenient to use the *rms* value of the spin precession frequency in this random field, ω . Thus we have the following physical picture of spin relaxation: the spin makes a precession around the (random) direction of the effective magnetic field with a typical frequency ω and during a typical time τ_c . After a time τ_c the direction and the absolute value of the field change randomly, and the spin starts its precession around the new direction of the field. After a certain number of such steps the initial spin direction will be completely forgotten. How this happens, depends on the value of the dimensionless parameter $\omega\tau_c$, which is the typical angle of spin precession during the correlation time. Two limiting cases may be considered:

$\omega\tau_c \ll 1$ (most frequent case)

The precession angle is small, so that the spin vector experiences a slow angular diffusion. During a time t , the number of random steps is t/τ_c , for each step the squared precession angle is $(\omega\tau_c)^2$. These steps are not correlated, so that the total squared angle after a time t is $(\omega\tau_c)^2 \cdot (t/\tau_c)$. The spin relaxation time may be defined as the time at which this angle becomes of the order of 1. Hence: $\tau_s \sim \omega^2\tau_c$. This is essentially a *classical* formula (the Planck constant does not enter), although certainly it can be also derived quantum-mechanically. Note, that in this case $\tau_s \gg \tau_c$.

$\omega\tau_c \gg 1$

This means that during the correlation time the spin will make many rotations around the direction of the magnetic field. During the time on the order of $1/\omega$ the spin projection transverse to the random magnetic field is (on the average) completely destroyed, while its projection along the direction of the field is conserved.

At this stage the spin projection on its initial direction will diminish 3 times. [Let the random magnetic field have an angle θ with the initial spin direction. After many rotations the projection of the spin on the initial direction will diminish as $(\cos \theta)^2$. In three

dimensions, the average of this value over the possible orientations of the random field yields $1/3$.] After time τ_c the magnetic field changes its direction, and the initial spin polarization will finally disappear. Thus in the case $\omega\tau_c \gg 1$ the decay of spin polarization is not exponential in time, and the process has two distinct stages, the first one has a duration $1/\omega$, and the second one has a duration τ_c . The overall result is: $\tau_s \sim \tau_c$. This consideration is quite general and applies to any mechanism of spin relaxation. We have only to understand the values of the relevant parameters ω and τ_c for a given mechanism.

Spin relaxation mechanisms

There are several possible mechanisms providing the fluctuating magnetic fields responsible for spin relaxation.

Elliott-Yafet mechanism

The electrical field, accompanying lattice vibrations, or the electric field of charged impurities is transformed to an effective magnetic field through spin-orbit interaction. Thus momentum relaxation should be accompanied by spin relaxation (Elliott, 1954; Yafet, 1963). For phonons, the correlation time is on the order of the inverse frequency of a typical thermal phonon. Spin relaxation by phonons is normally rather weak, especially at low temperatures. For scattering by impurities, the direction and the value of the random magnetic field depends on the geometry of the individual collision (the impact parameter). This random field cannot be characterized by a single correlation time, since it exists only during the brief act of collision and is zero between collisions. In each act of scattering the electron spin rotates by some small angle φ . These rotations are uncorrelated for consequent collisions, so the average square of spin rotation angle during time t is on the order of $\langle \varphi^2 \rangle (t/\tau_p)$, where τ_p is the momentum relaxation time and $\langle \varphi \rangle$ is the average of φ^2 over the scattering geometry. Thus $1/\tau_s \sim \langle \varphi^2 \rangle / \tau_p$. The relaxation rate is obviously proportional to the impurity concentration.

Dyakonov-Perel mechanism

The mechanism is related to the spin-orbit band splitting caused by the absence of inversion symmetry (Dyakonov and Perel, 1971a, 1972). For a given $\mathbf{p}$, let $\Omega(\mathbf{p})$ be the spin precession frequency in this field. It was shown theoretically (Dresselhaus, 1955) that for non-centrosymmetric semiconductors, like GaAs, this frequency is cubic in momentum and given by:

$$\Omega_x \sim p_x(p_y^2 - p_z^2), \Omega_y \sim p_y(p_z^2 - p_x^2), \Omega_z \sim p_z(p_x^2 - p_y^2), \quad (2)$$

The effective magnetic field changes in time because the direction of $\mathbf{p}$ varies due to electron collisions. Thus the correlation time is on the order of the momentum relaxation time, τ_p , and if $\Omega\tau_p \ll 1$, which is normally the case, we get: $1/\tau_s \sim \Omega^2\tau_p$.

In contrast to the Elliott-Yafet mechanism, now the spin rotates not during, but *between* the collisions. Accordingly, the relaxation rate increases when the impurity concentration decreases (i.e. when τ_p becomes longer). It happens that this mechanism is often the dominant one, both in bulk A^{III}B^V and A^{II}B^{VI} semiconductors, like GaAs, as well as in 2D structures.

Bir-Aronov-Pikus mechanism

This is a mechanism of spin relaxation of non-equilibrium electrons in *p*-type semiconductors due to the exchange interaction between the electron and hole spins or, expressing it otherwise, the exchange interaction between an electron in the conduction band and all the electrons in the valence band (Bir et al., 1976). This spin relaxation rate, being proportional to the number of holes, may become the dominant one in heavily *p*-doped semiconductors.

Relaxation via hyperfine interaction with nuclear spins

The electron spin interacts with the spins of the lattice nuclei, which are normally in a disordered state. Thus the nuclei provide a random effective magnetic field, acting on the electron spin. The corresponding relaxation rate is rather weak, but may become important for localized electrons, when other mechanisms, associated with electron motion, do not work.

Spin relaxation of holes in the valence band

The origin of this relaxation is in the splitting of the valence band into sub-bands of light and heavy holes. In this case, $\hbar\Omega(\mathbf{p})$ is equal to the energy difference between light and heavy holes for a given $\mathbf{p}$ and the correlation time is again τ_p . However, in contrast to the situation for electrons in the conduction band, we have now the opposite limiting case: $\Omega(\mathbf{p})\tau_p \gg 1$. So, the hole spin relaxation time is on the order of τ_p , which is very short. One can say that the hole "spin" $\mathbf{J}$ is rigidly fixed with respect to its momentum $\mathbf{p}$, and because of this, momentum relaxation leads automatically to spin relaxation. For this reason, normally it is virtually *impossible* to maintain an appreciable non-equilibrium polarization of bulk holes. However, Hilton and Tang (2002) have managed to observe the spin relaxation (on the femtosecond time scale) of both light and heavy holes in undoped bulk GaAs. The general theory of the

relaxation of spin, as well as helicity and other correlations between $\mathbf{J}$ and $\mathbf{p}$, for holes in the valence band was given by Dyakonov and Khaetskii (1984).

Influence of magnetic field on spin relaxation

In the presence of an external magnetic field $\mathbf{B}$, the spins perform a regular precession with a frequency $\Omega = g\mu B/\hbar$, and one should distinguish between relaxation of the spin component along $\mathbf{B}$ and the relaxation, or dephasing, of the perpendicular components. In the magnetic resonance literature it is customary to denote the corresponding longitudinal and transverse times as T_1 and T_2 respectively.

To understand what happens, it is useful to go to a frame rotating around $\mathbf{B}$ with the spin precession frequency Ω . In the absence of random fields, the spin vector would remain constant in the rotating frame. Relaxation is due to random fields in the rotating frame, and obviously these fields now rotate around $\mathbf{B}$ with the same frequency Ω . Thus random fields directed along $\mathbf{B}$ are the same as in the rest frame, and cause the same relaxation of the perpendicular spin components with a characteristic time $T_2 \sim \tau_s$. However the perpendicular components of the random field, which are responsible for the relaxation of the spin component along $\mathbf{B}$, do rotate. The importance of this rotation is determined by the parameter $\Omega\tau_c$, the angle of rotation of the random field during the correlation time. If $\Omega\tau_c \ll 1$, then rotation is of no importance, since the random field will anyway change its direction after a time τ_c . However, for $\Omega\tau_c \gg 1$ the rotating random field will effectively average out during the correlation time, resulting in a decrease of the longitudinal spin relaxation rate. A simple calculation gives:

$$\frac{1}{T_1} = \frac{1}{\tau_s} \frac{1}{1 + (\Omega\tau_c)^2} = \frac{\omega^2\tau_c}{1 + (\Omega\tau_c)^2}. \quad (3)$$

Interestingly, with increasing magnetic field the longitudinal spin relaxation rate changes from being proportional to τ_c to becoming proportional to $1/\tau_c$. Again, the above classical formula can be also derived quantum-mechanically. From the quantum point of view the longitudinal relaxation is due to flips of the spin projection on $\mathbf{B}$, which requires an energy $g\mu B$. Since the energy spectrum of the random field has a width $\sim 1/\tau_c$, the process becomes ineffective when $g\mu B \gg \hbar/\tau_c$, or equivalently, when $\Omega\tau_c \gg 1$. Ivchenko (1973) has calculated the influence of magnetic field on the Dyakonov-Perel spin relaxation. The result coincides with Eq. (2) with $\tau_c = \tau_p$, except that the spin precession frequency Ω is replaced by the (greater) electron cyclotron frequency, ω_c . The reason is that for this case the variation of the vector $\Omega(\mathbf{p})$ is primarily due to the rotation of the electron momentum $\mathbf{p}$ in magnetic field.

Spin relaxation of two-dimensional electrons and holes

Usually the Dyakonov-Perel mechanism is the dominant one. The relaxation rate is governed by the linear momentum dependence of the effective magnetic field, or the vector $\Omega(\mathbf{p})$, see above. The spin relaxation is generally anisotropic and depends on the growth direction (Dyakonov and Kachorovskii, 1986). As seen from Eq. (7), for quantum wells grown in the (001) direction the effective magnetic field lies in the 2D plane. As a consequence, the spin component perpendicular to the plane decays 2 times faster than the spin in-plane components.

More details on spin-orbit interaction in two dimensional systems can be found in Winkler's book (Winkler, 2003).

Hanle effect

Depolarization of luminescence by a transverse magnetic field, first discovered by Wood and Ellett (1924) (in their case it was the magnetic field of the Earth!) and studied in more detail by Hanle (1924), is effectively employed in experiments on spin orientation in semiconductors. The reason for this effect is the precession of electron spins around the direction of the magnetic field. Under continuous illumination, this precession leads to the decrease of the average projection of the electron spin on the direction of observation, which defines the degree of circular polarization of the luminescence. Thus the degree of polarization decreases as a function of the transverse magnetic field. Measuring this dependence under steady state conditions makes it possible to determine both the spin relaxation time and the recombination time. This effect is due to the precession of electron spins in a magnetic field $\mathbf{B}$ with the Larmor frequency Ω . This precession, along with spin pumping, spin relaxation, and recombination is described by the following simple equation of motion of the average spin vector $\mathbf{S}$:

$$\frac{d\mathbf{S}}{dt} = \boldsymbol{\Omega} \times \mathbf{S} - \frac{\mathbf{S}}{\tau_s} - \frac{\mathbf{S} - \mathbf{S}_0}{\tau} \quad (4)$$

where the first term on the *rhs* describes spin precession in a magnetic field ($\Omega = g\mu B/\hbar$), the second term describes spin relaxation, and the third one describes generation of spin by optical excitation ($\mathbf{S}_0/\tau$) and recombination ($-\mathbf{S}/\tau$). The vector $\mathbf{S}_0$ is directed along the exciting light beam, its absolute value is equal to the initial average spin of photo-created electrons. In the stationary state ($d\mathbf{S}/dt = 0$) and in the absence of a magnetic field, one finds:

$$S_z(B) = \frac{S_z(0)}{1 + (\Omega\tau^*)^2}, \quad \frac{1}{\tau^*} = \frac{1}{\tau} + \frac{1}{\tau_s}. \quad (5)$$

The effective time τ^* defines the width of the depolarization curve. Thus the spin projection S_z (and hence the degree of circular polarization of the luminescence) decreases as a function of the transverse magnetic field. Combining the measurements of the zero-field value $P = S_z(0)$ and of the magnetic field dependence in the Hanle effect, we can find the two essential parameters: the electron lifetime, τ , and the spin relaxation time, τ_s , under steady-state conditions.

Interconnections between spin and charge

Because of spin-orbit interaction, charge and spin are interconnected: there is a number of phenomena where an electrical current produces spin current and/or homogeneous spin polarization and vice versa. Generally, an electric current induces a transverse spin current leading to spin accumulation at the boundaries, or a uniform spin polarization, or both effects simultaneously. Inverse effects exist too.

Phenomenologically, all these effects can be derived from pure symmetry considerations, according to the general principle: *everything that is not forbidden by symmetry or conservation laws will happen*. The microscopic theory should provide the physical mechanism of the phenomenon under consideration, as well as the values of observable quantities.

Electric current inducing spin current (Spin Hall Effect)

Spin accumulation at the lateral boundaries of a current-carrying sample (the Spin Hall Effect) was predicted in 1971 by Dyakonov and Perel (1971b, 1971c), together with the Inverse Spin Hall Effect (Dyakonov and Perel, 1971b), which was observed for the first time in 1984 by Bakun et al. (1985). The name “Spin Hall Effect” was given by Hirsch (1999) who re-predicted this phenomenon 28 years later.

The first experimental observations of the direct Spin Hall Effect were reported by Kato et al. (2004a) and by Wunderlich et al. (2005). Related phenomena that have attracted much attention are the Spin Hall Magnetoresistance (Dyakonov, 2007) and the swapping effect - a mutual transformation of spin currents, introduced by Lifshits and Dyakonov (2009).

Electric current inducing homogeneous spin polarization

In gyrotropic systems (like Te crystals, or III-V quantum wells) the electric current can also generate *homogeneous* spin polarization. This effect was predicted by Ivchenko and Pikus (1978) for bulk Te crystals and observed by Vorob'ev et al. (1979).

In two dimensions this effect was treated theoretically by Vas'ko (1979), Vas'ko and Prima (1979), by Levitov et al. (1985), by Edelstein (1990), and by Aronov et al. (1991). Experimentally it was observed in quantum wells by Silov et al. (2004), by Ganichev et al. (2006), and also, for strained bulk materials, by Kato et al. (2004b).

Inversely, spin polarization in such systems can induce electric current as it was shown theoretically by Ivchenko et al. (1989). The first experimental demonstration of this effect, named the *spin-galvanic effect*, was reported by Ganichev et al. (2002). Furthermore, the interconnection between the spin polarization, spin current, and charge current is particularly pronounced under polarized radiation giving rise to photo-galvanic phenomena. The circular photo-galvanic effect was independently predicted by Ivchenko and Pikus (1978) and by Belinicher (1978). It was first observed in Te crystals by Asnin et al. (1978) and in quantum wells by Ganichev et al. (2001).

This kind of effects has been re-discovered theoretically several times. Hence, a large variety of different names exist labelling one and the same thing: appearance of non-equilibrium spin polarization induced by dc electric current in gyrotropic media with linear in p spin splitting of energy bands, and vice versa.²

Conclusion

Optical orientation of electron (and nuclear) spins in semiconductors is a well-developed field of research with many hundreds of publications. During more than 50 years since the first experiments, an enormous progress has been made in discovering and understanding the physical mechanisms involving various interactions between electron and nuclear spins in solids with optical radiation, electric and magnetic fields, and a large number of new and sometimes unexpected effects has been discovered.

²Some of the labels used are: current-induced spin polarization (CISP), inverse spin-galvanic effect (ISGE), current-induced spin accumulation (CISA), magneto-electric effect (MEE), kinetic magneto-electric effect (KMEE), Edelstein effect (EE), inverse Edelstein effect (IEE), and Rashba-Edelstein effect (REE).

Abstract

Raman spectroscopy is one of the main characterization techniques for graphene and related materials. It is a non-destructive technique that can give insight in the material's quality, the number of layers, and is sensitive to any changes in electric or magnetic fields, band structure and temperature, making it ideal to probe layered materials.

Key points

- Brief introduction to Raman scattering
- Explanation of the Raman spectrum of graphene/graphene layers and how it changes as function of doping, defects, and strain
- Summary of the capabilities of Raman spectroscopy of graphene
- Overview of the current challenges and general outlook

Introduction

A single layer of graphene (SLG) (Novoselov et al., 2004) can be seen by using a microscope if placed over a Si/SiO₂ thickness ~100 nm or ~300 nm (Casiraghi et al., 2007a). The SiO₂ layer acts as a cavity for the light and results in either constructive or destructive interference depending on its thickness (Casiraghi et al., 2007a). Fig. 1 shows the calculated optical contrast as function of laser wavelength and SiO₂ thickness with contrast maxima at ~100 and ~300 nm thickness for commonly used laser wavelengths between ~450 and ~600 nm. While imaging by optical contrast can give an idea of its thickness, it is not enough to get more quantitative information, such as doping, disorder, strain, etc.

Raman spectroscopy is a powerful characterization technique for carbons in general, ranging from fullerenes, nanotubes, graphitic carbons to amorphous and diamond-like carbons (Ferrari and Robertson, 2000; Tuinstra and Koenig, 1970; Dresselhaus et al., 2005; Dresselhaus et al., 1996). In graphene, Raman spectroscopy can now be routinely used to extract the number of layers, N, to estimate the type and amount of doping and strain, as well as to check the quality of graphene as it this spectroscopic technique is also sensitive to defects (Ferrari and Basko, 2013).

Brief overview of light scattering processes

Light scattering can be either elastic, i.e. the incident and scattered light have the same frequency, or inelastic, where the scattered light has a different frequency with respect to the incident light. In classical electrodynamics, when light impinges on a medium, electrons within that medium start to oscillate at the same frequency as the incident electromagnetic wave. This periodic perturbation of the electron cloud results in the creation of an oscillating dipole moment leading to the emission of light with the same frequency as the incident light, i.e. elastic scattering of light. Examples are Mie scattering (Mie, 1908) and Rayleigh

scattering (Strutt, 1871), depending on the particle size in the medium. Light scattering off particles larger than the wavelength and having a refractive index different from that of the continuous medium in which they are embedded is referred to as Mie scattering, which can be observed when sun light scatters from the water droplets within clouds. If the particle size is smaller than the wavelength of light, such as is the case for atoms or molecules, the process is called Rayleigh scattering. An example is the color of the sky, either blue during the day or red at sun rise or sunset, where light is scattered off the molecules in the atmosphere.

In the case of inelastic light scattering, the scattered light has a different frequency or energy with respect to the incident light. This process can be more conveniently described by quantum theory, whereas an electron absorbs a photon, leaving behind an empty space (a hole), and as a result is promoted to an energetically higher level. The electron can then either fall directly back to a lower level, while emitting a photon with energy corresponding to the energy level difference, or scatter with the lattice, i.e. create or annihilate/absorb a phonon, before recombining radiatively with a hole. Examples for inelastic light scattering are Brillouin and Raman scattering. While Brillouin scattering involves low frequency lattice vibrations, i.e. acoustic phonons, Raman scattering involves optical phonons in first order scattering processes (Brüesch, 1986).

The Raman scattering process was first theoretically predicted in 1923 by Austrian physicist Smekal (Smekal, 1923). The experimental proof was delivered in 1928 by Landsberg and Mandelstam (Landsberg and Mandelstam, 1928) in crystals and by Raman and Krishnan (Raman and Krishnan, 1928) in liquids. For his findings Raman was awarded the Nobel Prize in physics in 1930 (Nobel-Prize). Since then - and even more so after the invention of the laser in 1960 (Schawlow and Townes, 1958; Maiman, 1960) - Raman spectroscopy has become a standard materials characterization tool as it is non-destructive, fast and easy to use (Ferrari and Basko, 2013).

Raman scattering process

Raman scattering is the inelastic scattering between light, i.e. a photon, and matter. It involves the exchange of rotational or vibrational quanta of energy in molecules or the creation and annihilation of phonons with frequency Ω in solids (Cardona and Güntherodt, 1982). If light of frequency ω_L is incident on a material, most of the light is elastically scattered. This Rayleigh scattering process is shown in Fig. 2. From a classical point of view, light can be described as a propagating electromagnetic wave with $E(t) = E_0 \cos(\omega_L t)$ with amplitude E_0 and frequency ω_L . The electron cloud responds to the fast changing electric field and this will induce a dipole moment $\mu(t)$ proportional to the electric field of the incoming light (Yu and Cardona, 1996):

$$\mu(t) = \alpha E(t) = \alpha_0 E_0 \cos(\omega_L t) \quad (1)$$

where the proportionality constant α is the polarizability. This describes the ability of, e.g., molecules to be polarized, and depends on the relative position of the individual atoms. Atomic vibrations are confined to certain energetic levels and are quantized into phonons. The physical displacement of the atoms dQ about their equilibrium position associated with a phonon can be described as: $dQ = Q_0 \cos(\Omega t)$, where Ω is the phonon frequency and Q_0 is the displacement about the equilibrium position. A material's response to electromagnetic radiation depends on the atomic positions. The atomic displacements change the susceptibility, thus its polarization, depending on the phonon involved. At room temperature (RT) the atomic displacement is small

Fig. 2 Energy level diagram showing Rayleigh and Raman scattering (Stokes and anti-Stokes) processes. Blue lines depict absorption of a photon, while red lines depict emission of a photon. Non-resonant processes involve virtual states, while resonant scattering processes involve real states.

compared to the lattice constant. Therefore, the polarizability α can be approximated by a Taylor series expansion around the lattice displacement. Considering only first order terms we get:

$$\alpha = \alpha_0 + \left. \frac{\partial \alpha}{\partial Q} \right|_0 dQ + \dots = \alpha_0 + \left. \frac{\partial \alpha}{\partial Q} \right|_0 Q_0 \cos(\Omega t) \quad (2)$$

Inserting Eq. (2) in (1) gives:

$$\mu(t) = \alpha_0 E_0 \cos(\omega_L t) + \left. \frac{\partial \alpha}{\partial Q} \right|_0 E_0 Q_0 \cos(\Omega t) \cos(\omega_L t)$$

Using a trigonometric identity for the product of the cosine terms leads to

$$\mu(t) = \alpha_0 E_0 \cos(\omega_L t) + \frac{1}{2} \left. \frac{\partial \alpha}{\partial Q} \right|_0 E_0 Q_0 \{ \cos[(\Omega - \omega_L)t] + \cos[(\Omega + \omega_L)t] \} \quad (3)$$

The intensity of the scattered light I_{sc} is proportional to $|\ddot{\mu}|$, where $\ddot{\mu}$ is the second derivative of μ with respect to time, t :

$$I_{sc} \propto \cos^2(\omega_L) + \cos^2[(\omega_L + \Omega)t] + \cos^2[(\omega_L - \Omega)t] + \text{cross terms} \quad (4)$$

The first term corresponds to the *elastically* scattered light, i.e. Rayleigh scattering, since it only depends on ω_L , while the other two terms describe the inelastically scattered light, i.e. Raman scattering. Here we distinguish between Stokes (S) and anti-Stokes (AS) scattering, both named after Sir G. G. Stokes (Larmor, 1907). In S-scattering a phonon is created by energy transfer from the electron to the lattice resulting in the $(\omega_L - \Omega)$ term, meaning the scattered light has a lower frequency with respect to the incident light, while in AS-scattering a phonon is annihilated (or absorbed), giving the $(\omega_L + \Omega)$ term. The S and AS Raman scattering processes are depicted in Fig. 2. AS Raman scattering involves the absorption of a phonon. Consequently, the scattering process starts directly from a vibrational state as shown in Fig. 2.

At RT the AS-Raman peaks have lower intensity compared to S, but their intensity increases with rising temperature (T). This can be explained by considering the Bose-Einstein distribution, whereby the number of phonons in a certain energy state strongly depends on T, and increases with T (Kittel, 2005). If n_q is the phonon occupation number, then the S-Raman scattering intensity will be proportional to $n_q + 1$, since a phonon is created during the scattering process. For AS, we start at an excited (vibrational) state and a phonon is annihilated, giving rise to intensity proportional to n_q . Thus, the S/AS intensity ratio can be expressed as (Placzek, 1934; Krishnan and Narayanan, 1950):

$$\frac{I_{Stokes}}{I_{anti-Stokes}} = \left(\frac{\omega_L - \Omega}{\omega_L + \Omega} \right)^4 \exp\left(\frac{\hbar\Omega}{k_B T}\right), \quad (5)$$

where k_B is the Boltzmann constant, ω_L is the frequency of the laser light, Ω is the phonon frequency, $\hbar$ is the reduced Planck constant. By re-arranging Eq. (5) for T, the sample T can be determined by fitting the peak intensity of a peak on S and AS side of the Raman spectrum.

The intensity of the scattered light also strongly depends on whether we have a resonant or non-resonant process (Loudon, 1965). In a resonant process, real electronic states are involved, while in non-resonant Raman scattering virtual states are used to

describe the process. The intensity of the Raman scattered light depends on the polarization of the incident and scattered light as well as on the phonon involved in the scattering process. The symmetry of the phonon mode is incorporated in the so-called Raman tensor $\mathfrak{R}$. Introducing a unit vector in direction of the lattice displacement $\hat{Q}$ this term can be expressed as (Yu and Cardona, 1996)

$$\mathfrak{R} = \frac{\partial \alpha}{\partial Q} \bigg|_0 \hat{Q} \quad (6)$$

Assuming $\hat{e}_i$ and $\hat{e}_{sc}$ to be unit vectors of the polarization of the incoming and scattered light, the Raman intensity is proportional to $I \propto |\hat{e}_i \mathfrak{R} \hat{e}_{sc}|^2$ (Yu and Cardona, 1996). Thus, for Raman scattering to occur, the term $\frac{\partial \alpha}{\partial Q} \big|_0$ has to be non-zero, meaning the polarizability has to change. By doing polarization dependent measurements, the symmetry of the Raman tensor, thus that of the corresponding phonon, can be obtained (Cardona and Güntherodt, 1982). This is very useful for correct assignment of the Raman peaks.

During the scattering process, energy and momentum conservation have to hold: $\hbar\omega_L = \hbar\omega_{sc} \pm \hbar\Omega$ and $k_L = k_{sc} \pm q$, where $\hbar$ is the reduced Planck constant, ω_L , ω_{sc} , Ω are the frequency of the incident light, the scattered light and the phonon, respectively, and k_L , k_{sc} , q are the corresponding wave vectors and the phonon momentum. The wavevectors can be expressed in terms of wavelength λ via $k = 2\pi\lambda^{-1}$. The lattice constant of a material is of the order of a few Å, thus much smaller than λ (in the order of a few hundreds of nm), giving k_L , $k_{sc} \ll \pi a^{-1}$, which is the size of the first Brillouin zone (BZ), where a is the lattice constant. Combining this with the equations for energy and momentum conservation we can deduct that $q \ll \pi a^{-1}$ meaning $q \approx 0$. This is called the fundamental Raman selection rule, and tells us that the phonons contributing to first order Raman scattering stem from the BZ center. For higher order scattering processes, i.e. processes involving multiple phonons, the selection rule becomes $\sum q = 0$. So, in a second order Raman process, two phonons with equal but opposite momentum are contributing since $q + (-q) = 0$.

Raman spectroscopy of graphene and graphene layers

In real space, single layer graphene (SLG) has a hexagonal structure resulting in a hexagonal structure in reciprocal space as well, where Γ marks the BZ center and the high symmetry points at the corner are labelled as K and K', Fig. 3A. At these so-called Dirac points, SLG has a unique linear dispersion relation (Dirac cones).

In SLG there are two atoms per unit cell giving rise to six normal modes (two being doubly degenerate) at Γ with irreducible representation: $A_{2u} + B_{2g} + E_{1u} + E_{2g}$ (Nemanich et al., 1977). The E_{2g} and B_{2g} modes are both doubly degenerate, whereas the E_{2g} mode is Raman active and the B_{2g} is silent, i.e. neither Raman nor IR active (Nemanich et al., 1977). The A_{2u} and E_{1u} modes are both IR active modes (Ferrari and Basko, 2013).

The Raman spectrum of graphite and multilayer graphene consists of two different sets of peaks: those at higher wavenumbers, such as the D, G, 2D and 2D' modes due to in-plane vibrations, and those at low frequency, such as the shear (C) and layer breathing modes (LBMs), due to the relative movement of the whole atomic planes, either parallel or perpendicular (Ferrari and Basko, 2013; Tan et al., 2012), Fig. 4. In SLG only the first set of peaks is visible (Ferrari et al., 2006).

Fig. 3 (A) SLG structure in reciprocal space (BZ). The high symmetry points and a schematic of the electronic dispersion at K and K' (Dirac cones) are indicated. (B) Doubly degenerate E_{2g} mode and A_{1g} breathing mode giving rise to the G and D peak in SLG. (C) SLG Phonon dispersion. The red lines indicate the positions of Kohn anomalies. Fig. 4 Comparison of Raman spectra of pristine graphene, defective graphene and graphite.

The G peak $\sim 1580 \text{ cm}^{-1}$ arises from an E_{2g} phonon stemming from the Γ -point, Fig. 3B and C. The D peak, corresponding to an A_{1g} phonon (Fig. 3B), is due to the breathing mode of six-atom rings and requires a defect for its activation (Ferrari and Robertson, 2000; Thomsen and Reich, 2000; Tuinstra and Koenig, 1970) to fulfill the fundamental Raman selection rule. This peak is activated by an *intervalley* double resonance process (Thomsen and Reich, 2000), connecting K and K' , and comes from a transverse optical (TO) phonon at the K point, Fig. 3C. Due to the presence of a Kohn anomaly (Piscanec et al., 2004), i.e. a damping of the phonon dispersion (red lines in Fig. 3C), it is also highly dispersive with excitation energy shifting by $\sim 50 \text{ cm}^{-1} \text{ eV}^{-1}$ (Pocsik et al., 1998). Similarly, an *intravalley* double resonance scattering process at K or K' gives rise to another defect-activated peak, the D' peak. In defective graphene also the combination mode $D + D'$ starts to appear. The $2D$ and $2D'$ peaks are the second order modes of the D and D' peak, where the momentum conservation is fulfilled by scattering of two phonons with opposite wave vectors. Thus, these peaks do not require defects for their activation and are always present in the Raman spectrum of graphene (Ferrari et al., 2006; Basko et al., 2009). This means that only the G peak in the Raman spectrum of graphene fulfills the fundamental Raman selection rule directly as its origin is at the center of the Brillouin zone where $q = 0$. All scattering processes are depicted in Fig. 5.

Counting graphene layers: 2D peak and ultra-low frequency modes

The Raman peaks of graphene can be fitted with a Lorentzian line shape, which arises from a finite, homogeneous lifetime broadening. Here we use the following notation (Ferrari and Basko, 2013) to refer to the peak fitting parameters: 'I' for peak height (intensity), 'A' for peak area, 'Pos' for peak position and 'FWHM' for the full-width at half-maximum of the peak.

The Raman scattering process in SLG is always resonant due to its linear band structure. The band structure of SLG and multilayer graphene (MLG) is reflected in the shape of the 2D peak (Ferrari et al., 2006). In SLG, the 2D peak is one sharp peak that can be fitted with a single Lorentzian line, while in Bernal stacked bilayer graphene (BLG) it splits into four components following the evolution of the band structure, Fig. 6A and B. Thus, the 2D peak shape can be used to estimate N . However, beyond ~ 5 – 10 layers, the 2D peak will start looking like that of graphite, Fig. 6A, and the 2D peak shape cannot be used, alone, to estimate N correctly. Low frequency modes are far more sensitive to N , even beyond $N = 5$, Fig. 6C. For accuracy the resulting peak positions of C and/or LBMs can be calculated as the mean value of the fitted S/AS peak positions.

The C peak changes its position with N , Fig. 6D. Following a linear chain model where each layer is estimated as one mass coupled by a spring to the next mass (layer), the relation between the position of the C peak (in cm^{-1}) and N can be written as (Tan et al., 2012):

$$\text{Pos}(C)_N = \frac{1}{\sqrt{2\pi c}} \sqrt{\frac{\alpha}{\mu}} \sqrt{1 + \cos\left(\frac{\pi}{N}\right)} \quad (7)$$

where the pre-factor $(1/\pi c) \sqrt{\alpha/\mu}$ corresponds to $\text{Pos}(C)_\infty$ in graphite with $N \rightarrow \infty$, $\alpha \sim 12.8 \times 10^{18} \text{ Nm}^{-3}$ is the interlayer coupling constant, $\mu = 7.6 \times 10^{-27} \text{ kg \AA}^{-2}$ is the SLG mass per unit area and c is the speed of light in cm s^{-1} .

Thus, by knowing $\text{Pos}(C)$ in bulk graphite one can extract the interlayer coupling constant, thus get fundamental information about the interaction between the layers. This model can be applied to all layered materials (LMs), see e.g. refs. (Pizzi et al., 2021; Zhang et al., 2013).

Fig. 5 Raman scattering processes in SLG. The red shaded area within the linear dispersion relation shows the occupied states. The G peak arises from one phonon scattering. Depending on doping, some processes will no longer be allowed. The D' (intravalley scattering), D (intervalley scattering) and D + D' peak require defects for their activation. The two different processes for the D and D' peak depicted here give the largest contribution. The two-phonon (second order) modes, 2D and 2D' peak, do not require a defect. Schematics from Ref. The Raman spectrum of strained graphene

SLG can be stretched up to at least ~20% without breaking (Bunch et al., 2007; Lee et al., 2008). Strain in graphene has not only a major effect on its structure but also on its Raman spectrum. Strain can occur in different forms: Uniaxial (Mohiuddin et al., 2009; Yoon et al., 2011; Mohr et al., 2010; Huang et al., 2010), i.e. strain along one direction, and biaxial strain, i.e. isotropic strain (Ding et al., 2010; Zabel et al., 2012; Metzger et al., 2010). Both types can either be applied as tensile or compressive.

Fig. 6 (A) 2D peak as function N. (B) For BLG, the 2D peak splits into 4 components. (C) Ultra-low frequency and G peak region of graphene layers. (D) Fitted C and G peak positions. In general, compressive strain results in an upshift of all Raman peaks, arising from the shortening of the interatomic bond lengths, while tensile causes a downshift, due to the elongation of the bond lengths resulting in a weakening of the vibrational modes. Biaxial strain preserves the hexagonal symmetry in SLG, i.e. it only leads to an isotropic expansion or compression of the hexagonal lattice, resulting in a linear peak shift. The linear change in peak position or frequency $\partial\omega = \partial\omega_G/\partial\epsilon \approx -57 \text{ cm}^{-1}/\%$ for the G peak and $\partial\omega_{2D}/\partial\epsilon \approx -140 \text{ cm}^{-1}/\%$ for the 2D peak (Zabel et al., 2012; Mohiuddin et al., 2009). Unless induced intentionally it is very unlikely to find biaxial strain in graphene samples. Uniaxial strain also results in linear peak shifts (Fig. 7), however it will break the hexagonal symmetry, which has an effect on the Raman peak shape. The G peak is a doubly degenerate mode and uniaxial strain makes both components visible: The peak splits into two components G^+ and G^- , one parallel and one perpendicular to the direction of applied strain (Mohiuddin et al., 2009), Fig. 7A–C. The rate of change is (Mohiuddin et al., 2009): $\partial\omega_{G^+}/\partial\epsilon \approx -10.8 \text{ cm}^{-1}/\%$ and $\partial\omega_{G^-}/\partial\epsilon \approx -31.7 \text{ cm}^{-1}/\%$ for the G peak and $\partial\omega_{2D}/\partial\epsilon \approx -64 \text{ cm}^{-1}/\%$ for the 2D peak. A similar splitting of the 2D peak has been reported when the uniaxial strain exceeds $\sim 0.5\%$ and is applied along a high-symmetry axis

(Huang et al., 2010; Mohr et al., 2010; Yoon et al., 2011), Fig. 7D and E. The 2D peak arises from an intervalley scattering process connecting K and K' points. Considering the structure of graphene, each K point has three neighboring K' points, leading to three contributions to the scattering process. Fig. 7F shows a schematic depicting the possible scattering processes for the 2D peak in strained graphene. The relative position of the Dirac points has been disturbed such that the three scattering mechanisms connecting K and K' are no longer identical (Huang et al., 2010; Yoon et al., 2011). In the example shown in Fig. 7F two of the three possible scattering mechanism lead to one 2D peak component, while the remaining one gives rise to the second 2D peak component (red and blue arrows in Fig. 7F), depending on the direction of strain either parallel or perpendicular to the armchair edge in graphene.

The Raman spectrum of doped graphene

Most graphene samples produced by either micromechanical cleavage (MC), chemical vapor deposition (CVD), liquid phase exfoliation (LPE) or carbon segregation from SiC or metal substrates are doped due to the sensitivity of graphene to adsorbates, e.g. moisture, and/or due to the interaction with the underlying substrate (Bonaccorso et al., 2012; Backes et al., 2020). Doping can also be applied on purpose either electrically or chemically and has a marked effect on the Raman spectrum of (Basko et al., 2009; Das et al., 2008; Bruna et al., 2014; Kalbac et al., 2010; Casiraghi et al., 2007b): In doped SLG Pos(G) increases, while FWHM(G) decreases for both electron (e) and hole (h) doping, see Fig. 8A and C. The increase in Pos(G) is due to a non-adiabatic removal of the Kohn anomaly at Γ , while the decrease of FWHM(G) is due to Pauli blocking of the phonon decay channel into e-h pairs when the e-h gap is higher than the phonon energy, and saturates when the Fermi energy, E_F , is bigger than half the phonon energy (Basko et al., 2009; Das et al., 2008). The 2D peak, allows distinguishing between e and h doping, as Pos(2D) increases for h doping and decreases for e doping (Das et al., 2008), Fig. 8B. This can be explained by taking the change of the equilibrium lattice parameter into account with a consequent stiffening/softening of the phonon modes, as a result of h and e doping, respectively. Both, intensity and area ratios, $I(2D)/I(G)$ and $A(2D)/A(G)$ depend on E_F . The ratios are maximum for $E_F = 0$, and decrease with increasing E_F (Basko et al., 2009; Das et al., 2008), Fig. 8D. Using the fitting parameters Pos(G), FWHM(G), Pos(2D), $I(2D)/I(G)$ and $A(2D)/A(G)$ with the corresponding graphs as function of E_F presented in refs. (Basko et al., 2009; Das et al., 2008), E_F can be extracted from the Raman spectrum.

Additional effects occur for high doping levels ~ 0.9 eV. In this case an enhancement of the G peak intensity $I(G)$ can be observed (Zhao et al., 2011). Doping changes the occupation of electronic states and since transitions from an empty state to a filled state are impossible (Pauli exclusion principle), this can exclude some of the BZ regions from contributing to the Raman matrix element

(Zhao et al., 2011). Because of suppression of destructive interference this leads to an enhancement of the G peak when $|E_F|$ matches half of the laser excitation energy $\hbar\omega_L/2$ (Zhao et al., 2011). At high doping the 2D peak is suppressed when the conduction band becomes filled at the energy probed by the laser (Zhao et al., 2011), Fig. 9A. There are 3 cases that can occur in highly doped samples (Ferrari and Basko, 2013): (i) the energy of the scattered (subscript 'Sc') and incoming photon (subscript 'L') are larger than twice E_F , i.e. $\omega_L, \omega_{Sc} > 2|E_F|/\hbar$. In this case the 2D peak scattering mechanism is allowed, Fig. 9B; (ii) $\omega_{Sc} < 2|E_F|/\hbar < \omega_L$, the photon absorption is allowed but the phonon emission is excluded by Pauli blocking; (iii) $\omega_L, \omega_{Sc} < 2|E_F|/\hbar$ both photon absorption and phonon emission are blocked.

The Raman spectrum of defected graphene

There are many production methods for graphene, such as MC, CVD, LPE, etc. (Bonaccorso et al., 2012; Backes et al., 2020) and the quality may vary depending on the production technique. E.g. MC SLG is still thought to give the most intrinsic, defect-free and clean samples (Purdie et al., 2018). High quality samples with RT mobility $\sim 70,000 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$ in single crystal CVD and $30,000 \text{ cm}^2 \text{V}^{-1} \text{s}^{-1}$ in polycrystalline CVD can be achieved by using optimized transfer processes (De Fazio et al., 2019). A measure for quality is the number of defects. Anything that breaks the hexagonal symmetry in graphene can be called a defect. Defects in graphene can occur as chemical adsorbates, edges or structural defects, such as vacancies. Perfect zig-zag edges in graphene cannot produce a D peak (Casiraghi et al., 2009; Cançado et al., 2004).

Raman spectroscopy in SLG is sensitive to defects and additional peaks appear. Ref. (Ferrari and Robertson, 2000) introduced a three-stage model of amorphisation going from stage 1: perfect SLG/graphite to nanocrystalline graphene, stage 2: nanocrystalline graphene to low- sp^3 amorphous carbon and stage 3: low- sp^3 amorphous carbon to highly disordered carbon, i.e. tetrahedral amorphous carbon. Here we will focus on stage 1, where the Raman spectrum evolves as follows:

1. The D peak appears and the ratio of D to G peak intensities, $I(D)/I(G)$, increases
2. The D' peak appears
3. All peaks broaden
4. The D + D' peak appears
5. At the end of stage 1 the G and D' peak are so wide that it is sometimes more convenient to consider them as a single, upshifted, wide G peak at 1600 cm^{-1}

Fig. 10 plots the evolution of the Raman spectrum of defected SLG within stage 1. A correlation between the intensity ratio $I(D)/I(G)$ and the average crystal size L_a was first suggested by Tuinstra and Koenig (1970):

$$\frac{I(D)}{I(G)} = \frac{C(\lambda)}{L_a} \quad (8)$$

where C is a proportionality constant depending on the laser wavelength λ , and $C(514 \text{ nm}) \sim 4.4 \text{ nm}$ (Tuinstra and Koenig, 1970; Knight and White, 1989).

Initially this was interpreted in terms of phonon confinement: the intensity of the forbidden process would be ruled by the 'amount of lifting' of the selection rule (Tuinstra and Koenig, 1970). Now we know that the D peak is produced only in a small region of the crystal near a defect or an edge (Casiraghi et al., 2009). For a nanocrystallite, $I(G)$ is proportional to the sample area,

Fig. 10 Evolution of SLG Raman spectrum for increasing amount of defects (stage 1) introduced by Ar^+ bombardment. Reprinted with permission from Cançado LG, Jorio A, Ferreira EHM, Stavale F, Achete CA, Capaz RB, Moutinho MVO, Lombardo A, Kulmala TS, and Ferrari AC (2011) Quantifying defects in graphene via Raman spectroscopy at different excitation energies. *Nano Letters* 11: 3190–3196. Copyright 2011 American Chemical Society.

$\propto L_a^2$, while $I(D)$ is proportional to the overall length of an edge, which scales as $\propto L_a$ (Ferrari and Basko, 2013) and thus $I(D)/I(G) \propto 1/L_a$. In stage 1, for a sample with defects, $I(D)$ is proportional to the total number of defects probed by the laser spot. Therefore for an average interdefect distance L_D and laser spot size L_L there are on average $(L_L/L_D)^2$ defects in the area probed by the laser spot and $I(D) \propto (L_L/L_D)^2$ (Ferrari and Basko, 2013). On the other hand, $I(G)$ is proportional to the total area probed by the laser spot $\propto L_L^2$, thus $I(D)/I(G) = C''(\lambda)/L_D^2$. This gives $C''(\lambda)/L_D^2 = I(D)/I(G) = C(\lambda)/L_a$ (Ferrari and Basko, 2013). However, for an increasing amount of defects the Tuinstra-Koenig relation will no longer hold (Ferrari and Robertson, 2000), as in this case $I(D)$ starts to decrease. The D peak is due to a breathing mode in 6-atoms rings (Ferrari and Robertson, 2000). With increasing amount of defects these rings will start to break and, as a result, $I(D)$ will decrease, which is the onset of stage 2.

Taking the excitation energy dependence (E_L^4) of the Raman peak intensities into account, the following relation for the interdefect distance has been extracted (Cançado et al., 2011):

$$L_D^2 [\text{nm}^2] = \frac{(4.3 \pm 1.3) \times 10^3}{E_L^4 [\text{eV}^4]} \left(\frac{I(D)}{I(G)} \right)^{-1} \quad (9)$$

with the relation $n_D [\text{cm}^{-2}] = 10^{14}/(\pi L_D^2)$, the defect concentration n_D can be related to $I(D)/I(G)$ (Cançado et al., 2011):

$$n_D [\text{cm}^{-2}] = (7.3 \pm 2.2) \times 10^9 E_L^4 [\text{eV}^4] \left(\frac{I(D)}{I(G)} \right) \quad (10)$$

Eqs. (9) and (10) can then be used directly to estimate the interdefect distance and corresponding defect concentration in SLG by calculating $I(D)/I(G)$ from the fitted D and G peaks. These relations are limited to Raman active defects. Perfect zig-zag edges (Beams et al., 2011; Casiraghi et al., 2009), charged impurities (Casiraghi et al., 2007b; Das et al., 2008), intercalants (Zhao et al., 2011) and uniaxial or biaxial strain (Mohiuddin et al., 2009; Lee et al., 2008; Proctor et al., 2009; Zabel et al., 2012) do not generate a D peak. Other Raman signatures can be used for these ‘silent’ defects.

Eqs. (8) and (9) are valid for undoped SLG. However, most samples are not intrinsic and show $E_F \sim 200\text{--}500$ meV (Bruna et al., 2014). In the combined case of defects and doping a modified formula has to be used to correctly estimate the defect concentration and interdefect distance, due to the E_F dependence of $I(D)$. Ref. Bruna et al. (2014) showed that $I(D)$ decreases as E_F increases, Fig. 11, which would result in an underestimation of defects in doped SLG. By including the correction for the doping dependence of $I(D)$, Eqs. (9) and (10) become (Bruna et al., 2014):

$$L_D^2 [\text{nm}^2] = \frac{(1.2 \pm 0.3) \times 10^3}{E_L^4 [\text{eV}^4]} \left(\frac{I(D)}{I(G)} \right)^{-1} \{E_F [\text{eV}]\}^{-(0.54 \pm 0.04)} \quad (11)$$

and

$$n_D [\text{cm}^{-2}] = (2.7 \pm 0.8) \times 10^{10} E_L^4 [\text{eV}^4] \left(\frac{I(D)}{I(G)} \right) \{E_F [\text{eV}]\}^{(0.54 \pm 0.04)} \quad (12)$$

The doping dependence of the D peak intensity can be explained by taking the scattering rate or line broadening energy $\gamma = \hbar\tau^{-1}$ into account, where τ is the lifetime of an electronic state (Basko et al., 2009). In the presence of defects and doping the total scattering rate γ_{tot} is governed by electron-phonon interactions as well as scattering due to defects and e-e interactions, which in turn strongly depends on the E_F . It is given by (Bruna et al., 2014): $\gamma_{tot} = \gamma_{e-ph} + \gamma_D + \gamma_{ee}(E_F)$, where $\gamma_{ee}(E_F) = 0.06|E_F|$ (Basko et al., 2009). Thus, for increasing E_F , γ_{ee} will increase, and so will γ_{tot} . A higher scattering rate indicates a shorter lifetime, which, in turn, results in an increase in peak width and decrease in peak intensity. Eqs. (11) and (12) are valid for defects within stage 1 and for $E_F < E_L/2$ in order to avoid Pauli blocking (Bruna et al., 2014).

Magnetic fields

Magnetic fields have also an effect on the Raman spectrum of graphene. In the presence of a magnetic field, electronic trajectories will become circular, thus the backscattering condition of the Raman scattering process will be modified, such that the emitted phonons have smaller momenta (Ando, 2007; Goerbig et al., 2007). Ref. (Faugeras et al., 2010) observed a shift toward lower wavenumbers and a broadening of the 2D peak in SLG when applying a perpendicular magnetic field up to 30 T. In the presence of such a strong magnetic field the electronic states are quantized into discrete levels, called Landau levels (Kittel, 2005). Raman spectroscopy can also be used to probe those Landau levels and extract the Fermi velocity (Ferrari and Basko, 2013). Without magnetic field, electronic excitations in SLG have a continuous spectrum (Wallace, 1947). In the presence of a magnetic field, as result of this electronic quantization, inelastic scattering of photons occurs due to inter-Landau level transitions (Faugeras et al., 2011) resulting in sharp B-field dependent peaks where, instead of a phonon, an e-h pair is emitted (Kashuba and Fal'ko, 2012; Kashuba and Fal'ko, 2009; Mucha-Kruczyński et al., 2010). Applying magnetic fields can also be used to estimate the e-phonon coupling and probe the electronic Landau levels (Faugeras et al., 2011; Kim et al., 2012; Kossacki et al., 2011).

Key issues

While acquiring Raman spectra is not particularly difficult, the data analysis needs to be done considering the contribution of different influences, such as strain, doping, defects, etc. Instead of taking single point spectra, Raman measurements are often performed as mapping, where spectra are recorded in a grid pattern across areas of several $\sim \mu\text{m}^2$. Having a high spatial resolution is important for Raman mapping. The laser spot size, thus the spatial resolution, in conventional Raman spectroscopy is dictated by the diffraction limit of light, in turn proportional to the laser wavelength, thus of the order of $\sim 1 \mu\text{m}$ (Cardona and Güntherodt, 1982).

To analyze small flakes ($< 1 \mu\text{m}$) with weak Raman signals, enhanced Raman scattering techniques, such as surface enhanced Raman scattering (SERS) (Kneipp et al., 2006) or tip-enhanced Raman scattering (TERS) can be used (Stöckle et al., 2000; Cao and Sun, 2022; Hartschuh et al., 2003). Both techniques exploit surface plasmons excited in metallic nanostructures by the incident radiation field of the laser, whereas in TERS the metallic nanostructure is provided by the apex of an atomic force microscopy tip

coated with a noble metal such as Au or Ag (Cao and Sun, 2022). With TERS, samples can be raster scanned with very high spatial resolution around tens of nm or less. Information can be derived combining topography with Raman at each raster point (Cao and Sun, 2022). SLG is ideal to study SERS effects of differently shaped and sized plasmonic nanostructures (Schedin et al., 2010; Lee et al., 2011). TERS has also been used to study twisted BLG (Gadelha et al., 2021), extracting the moiré wavelength and imaging different stacking regions (Gadelha et al., 2021). TERS can be used for LMs in general, to identify local inhomogeneities, such as local strain, doping or defects (Malard et al., 2021; Rabelo et al., 2020).

Conclusion

We have given an overview of Raman scattering in graphene. We have discussed how Raman spectroscopy is sensitive to the number of layers and structural defects as well as external influences such as doping, strain and magnetic fields. Raman spectroscopy is a powerful technique to extract quantitative information about the quality of graphene, its doping, and type and amount of strain, crucial for further processing graphene for any kind of device (Backes et al., 2020). It is key for quality control when moving toward industrial scale production of graphene (Backes et al., 2020). Raman spectroscopy has also been employed to study device performances and to understand their working principle. E.g. it was used to shed light on the charge-discharge process of graphene-based energy storage devices (Share et al., 2016). Raman spectroscopy continues to be used for fundamental material studies (Cong et al., 2020).

Raman spectroscopy is a prime characterization techniques for all types of carbons and contributed significantly to the understanding of graphene and LMs. However, there are over 1800 exfoliable or potentially exfoliable LMs (Mounet et al., 2018), of which only a small fraction has been studied so far. Raman spectroscopy is already being used to characterize LMs beyond graphene and to study the interaction between different LMs in heterostructures in the high and low frequency range. E.g. Raman spectroscopy has been used to study magnetic ordering in magnetic LMs (Kim et al., 2019).

Other advanced Raman techniques such as coherent anti-Stokes Raman scattering (CARS) are emerging for the characterization of LMs (Virga et al., 2019). CARS is a non-linear optical process that exploits the interaction between two laser pulses and is used for imaging samples. As for conventional Raman scattering, the first laser beam ‘pump’, ω_p , will cause S-Raman scattering, ω_s , creating a phonon, Fig. 12. This phonon can then be used directly for an AS-Raman process under the condition that the correlated photon energies (ω_p) match (Virga et al., 2019), Fig. 12. During this process the interaction of laser pulses and sample results in the generation of vibrational coherences, i.e. the atoms oscillate with the same phase, which in turn can lead to a signal enhancement of several orders of magnitude (Virga et al., 2019). CARS is particularly interesting for biological research due to its marker free imaging and ability to suppress fluorescence that would otherwise overshadow the Raman signal of the sample (Begley et al., 1974).

Abstract

Graphene is a material with exceptional electronic properties, only comparable to the best and cleanest semiconductors. Most semiconductors have a bandgap which is of the order of 1 eV, i.e. much larger than the thermal energy at room temperature. Confining charge carriers to reduced dimensions mostly relies on this bandgap. Graphene is a promising material to host individual charge carriers and spins for qubit applications with long coherence times. However, single-layer graphene does not have a bandgap and hence similar gating schemes as they have been successful to confine carriers in materials such as Si and GaAs are not feasible. In this review we describe how quantum confinement of excellent quality can be achieved in bilayer graphene, that has an electric field-tunable bandgap. We discuss quantized conductance in one-dimensional channels, Coulomb blockade in zero-dimensional islands called quantum dot as well as controlled single hole and single electron occupation of these dots. We close by discussing how spin and valley qubits in graphene could become useful objects for physics studies as well as for quantum information applications.

Key points

- A gap can be opened in bilayer graphene by suitable back and top-gate voltages
- If the Fermi energy is positioned in the gap current is completely suppressed
- Using patterned electrodes one can define lateral confinement potentials
- Quantum point contacts display quantized conductance
- Quantum dots show high-quality Coulomb blockade
- Using transport spectroscopy in magnetic field the spin and valley degrees of freedom for each carrier number can be determined
- Charge detectors can be built using the same gating technology
- Spin coherence times exceeding 50 ms are measured using spin-to-charge conversion

Introduction

Graphene displays excellent electronic properties. For example, the experimentally detected high-quality fractional quantum Hall states (Bolotin et al., 2009) even in CVD-grown samples (Schmitz et al., 2020) compare with the best transport data in AlGaAs-GaAs heterostructures, the workhorse for high-mobility electron transport for the last 30 years. Graphene has become a versatile material to investigate novel physics in two-dimensional systems. To further confine carriers to one-dimension, so-called quantum wires, or even zero-dimensional systems, so-called quantum dots, the potential landscape in which the charge carriers reside needs to have barriers. The simplest way is to etch the material away in areas, where carriers should not be. In graphene this technological approach has worked to some extent, but in the end was limited by the charges and imperfections occurring at the sample edges (Bischoff et al., 2015). In semiconductors the Fermi level at a surface is typically pinned to some midgap energy. For a free surface this means that carriers are depleted away from the surface and occupy bulk sites where the Fermi level is above (below) the conduction (valence) band edge. Graphene being a semi-metal without a gap leads to the peculiar situation that the electronic wavefunction of the charge carriers extends all the way to an edge and side depletion does not occur. In this sense graphene combines the properties of a metal, namely no surface (side) depletion, with the low carrier density and therefore large Fermi wavelength of a semiconductor.

The best quantum devices in semiconductors are obtained by so-called split-gate techniques. This technique was introduced for quantum point contacts in AlGaAs-GaAs heterostructures (van Wees et al., 1988; Wharam et al., 1988). Split-gates were patterned

between the source and drain electrodes. The carrier density below the split gates was depleted by suitable gate voltages such that the current had to flow through the narrow one-dimensional channel between the split gates. This led to the discovery of quantized conductance in one-dimension (van Wees et al., 1988; Wharam et al., 1988). The general use of split gates as well as more sophisticated double layer gating techniques are now routinely used to define zero-dimensional systems or quantum dots in GaAs, Si and Ge (Zwerver et al., 2022). Such an approach fundamentally fails in single layer graphene because of the absence of gap. Charge carriers can not be depleted by gate electrodes.

Bilayer graphene comes to the rescue, since a bandgap can be opened by vertical electric fields (Oostinga et al., 2008). Typical bandgaps are 50–100 meV for displacement fields of order 1 V/nm. For measurements these bandgaps are expected to be large enough to create barriers that the carriers cannot overcome by thermal excitation if the experiments are performed at temperatures of 1 K or below. While the bandgaps were detected and quantified both in transport and optical measurements, the electrical resistance across a gate-defined barrier remained low for many years as reported by many groups, see e.g. (Zhu et al., 2017).

The difference was made by using a graphite back gate rather than a metallic back gate (Overweg et al., 2018a). This way resistances across gate barriers larger than 10^{10} Ohm were measured. Using split-gate electrodes a narrow one-dimensional channel was realized. In contrast to semiconductors, where the bandgap is independent of gate voltages, an additional top gate on top of the constriction created by the split gates was used to tune the electronic width of the channel and observe quantized conductance in graphene (Overweg et al., 2018a). This technology was further developed over the years to fabricate highly tunable quantum devices, build graphene-based qubits and measure their lifetimes.

One-dimensional systems in graphene

Fig. 1 shows a schematic of a device which was used to measure quantized conductance. The bilayer graphene was produced in a usual exfoliation process using a graphite sample. In a subsequent stacking process the bilayer graphene was encapsulated by hexagonal boron nitride (hBN) layers and then placed on a graphite back gate. The whole stack was placed on an oxidized Si substrate. Source and drain edge contacts were made followed by the definition of split gates that leave a gap between them open. Finally, a layer of Al_2O_3 was deposited by atomic layer deposition followed by a channel gate that allows the tuning of the Fermi energy in the one-dimensional channel defined between the split gates.

The conductance between source and drain was measured as a function of voltages applied to split gates and back gate (Overweg et al., 2018a). The gate voltages were adjusted to maximize the gap opening in bilayer graphene and keep the Fermi energy in the gap. This way the carrier gas is depleted in the regions of bilayer graphene covered by the split-gates and the current will flow through the opening, called quantum point contact, defined by the split gates. In quantum point contacts realized on GaAs-AlGaAs heterostructures one would then tune the split gates to even more negative voltage to deplete the narrow channel as a consequence of the fringing electric fields emanating from the split gates. This is not possible in the configuration shown in Fig. 1, since tuning the split gate voltages would move the Fermi energy in the regions below the split gates out of the bilayer graphene bandgap and confinement would be lost. One therefore needs another tuning parameter, which is the additional channel gate shown in orange in Fig. 1. In the regions where it is above one of the split gates it will not affect the carrier gas in graphene because of screening. The voltage applied to the channel gate will only affect the carriers directly in the one-dimensional channel.

Fig. 2 shows the sample conductance versus channel gate voltage V_{ch} while keeping back gate and split gate voltages constant, as described above (for details see Lee et al., 2020). For this particular configuration the bulk of the sample as well as the one-dimensional channel was occupied with electrons. For negative channel voltages (here below -6.5 V) the one-dimensional channel is depleted and the entire device is pinched off. For channel voltages more positive than the pinch-off voltage of the channel the conductance starts to increase and shows plateaus separated by $\Delta G = 4 e^2/h$.

Such quantized conductance plateaus have been observed in semiconductor one-dimensional channels more than 30 years ago (van Wees et al., 1988; Wharam et al., 1988). In that case the plateaus were quantized in units of $2 e^2/h$, where the factor of 2 arose

Fig. 1 Sample layout. A bilayer graphene flake is encapsulated in hexagonal boron nitride (hBN). It is contacted by a source and drain contact and has a graphite back gate (gray) below, two split gates (yellow) and a channel gate (orange) on top. The channel gate is separated from the split gates by a dielectric layer of Al_2O_3 . Adapted from Ref. Overweg H, Eggimann H, Chen X, Slizovskiy S, Eich M, Pisoni R, Lee Y, Rickhaus P, Watanabe K, Taniguchi T, Fal'ko V, Ihn T, and Ensslin K (2018a) Electrostatically induced quantum point contacts in bilayer graphene. *Nano Letters* 18: 553.

Lee Y, Knothe A, Overweg H, Eich M, Kurzmann A, Taniguchi T, Wantanabe K, Fal'ko V, Ihn T, Ensslin K, and Rickhaus P (2020) Tunable valley splitting due to topological orbital magnetic moment in bilayer graphene quantum point contacts. *Physical Review Letters* 124: 126802.

from spin degeneracy. When graphene became available it seemed obvious that quantized conductance should also be observable in one-dimensional channels. Despite different technological approaches it took much longer than expected to reach this goal. The data shown in Fig. 2 shows one important aspect of graphene, which directly reflects its peculiar bandstructure. The honeycomb arrangement of the C atoms in real space means that the primitive unit cell contains two atoms. As a consequence there are two inequivalent points in reciprocal space, the so-called K and K' points, leading to an additional valley degeneracy. The factor of 4 in the conductance quantization in graphene directly reflects spin and valley degeneracy.

The bandstructure of graphene offers more surprises compared to the relatively simple parabolic band dispersion in most semiconductors. For large displacement fields in bilayer graphene, which are required to maximize the gap of the insulating regions, the band dispersion becomes Mexican hat-like and topological effects become relevant (McCann et al., 2007). This leads to peculiar magnetic field dependencies of the conductance plateaus (Overweg et al., 2018b) very different from what has been observed in semiconductors.

Quantum dots in graphene

Quantum dots in semiconductors are among the contenders for a successful qubit-based technology. High quality quantum dots in graphene that can be controlled down to the single carrier regime have become available within the last 5 years. Fig. 3 shows a schematic of the device. The vertical structure is similar to what is shown in Fig. 1 for the one-dimensional system. The main difference here is that the channel defined by the split gates is elongated and the Fermi energy along the channel can be locally controlled by various finger gates. The tuning of back gate and split gates is similar as in the one-dimensional case. The

Fig. 3 3D sketch of part of the device showing the different layers of gates and dielectrics. Edge contacts to the bilayer are colored in yellow, split gates are shown in green, and the finger gates are shown in blue. Adapted from Ref. Eich M, Herman F, Pisoni R, Overweg H, Lee Y, Rickhaus P, Watanabe K, Taniguchi T, Sigrist M, Ihn T, and Ensslin K (2018a) Spin and valley states in gate-defined bilayer graphene quantum dots. *Physical Review X* 8: 031023.

corresponding voltages are adjusted such that the displacement field-induced energy gap is maximized and the Fermi energy is in the gap. This forces any current between source and drain contact to flow in the channel formed between the split gates. The sign of the charge of the carriers, i.e. electrons or holes, in the bulk of the sample as well as in the one-dimensional channel depends on the sign of the back gate voltage. Once voltages on split gates and back gate are adjusted, the Fermi energy along the one-dimensional channel can be locally controlled by the voltages applied to the finger gates, for details see Eich et al. (2018a).

Fig. 4 shows the conductance measured through the one-dimensional channel while sweeping one of the finger gates (see Ref. Garreis et al., 2021). The measurement is similar as in Fig. 2, but now the bulk of the sample as well as the channel contain holes. As the finger gate voltage (V_{QD} in Fig. 4) is made more positive, first all holes are depleted from the channel and the channel is pinched off. For further more positive voltages, the Fermi energy passes the conduction band edge below the finger gates and electrons enter this local potential minimum one-by-one. The conductance traces in Fig. 4 show resonances, each indicating the addition of one electron to the potential minimum, which we call a quantum dot.

Traces like the one in Fig. 4 have been recorded for metallic islands and quantum dots in various semiconductor environments. In very clean systems, such as GaAs and Si, single charge occupancy has been reported (Ciorga et al., 2000). The data shown in Fig. 4 for graphene is as clean as in state-of-the-art semiconductor dots. The horizontal axes, i.e. the voltage applied to the finger gate, is approximately proportional to energy. The peaks are roughly equidistant which reflects the fact that the main energy cost to add an electron to the system is the charging energy. As the dot is filled with electrons, the bare confinement potential is screened and becomes wider and consequently the charging energy becomes smaller, as the overall capacitance becomes larger. There are special situations, labelled by vertical arrows in Fig. 4, where the peak spacing is larger than the spacing between neighboring peaks. In this case a new orbital level is occupied and an additional orbital energy cost arises upon adding an electron. For a circularly symmetric potential, as it is roughly the case for the sample investigated in Fig. 4, the first orbital state is expected to be s-like. Because of spin degeneracy and valley degeneracy (see discussion for one-dimensional channels in graphene in previous section) one can fill the first four electrons into the first orbital state. The next orbital state is p-like and therefore two-fold degenerate. Considering again spin and valley degeneracies one arrives at a total degeneracy of $8 = 2 \times 2 \times 2$.

The data in Fig. 4 shows that the next degeneracy should be 12. Here another important parameter of the graphene band structure enters the considerations. Low energy approximations give rise to Dirac cones in case of monolayer graphene and a rotationally symmetric parabolic dispersion in case of bilayer graphene. For high energies the bandstructure must reflect the underlying symmetry of the lattice which is hexagonal. This leads to distortions of the circular constant energy surfaces and is called trigonal warping. In the case of large displacement fields, as they are present in these quantum dot devices, the originally high energy characteristics of the band structure also influence the low energy dispersion. As the quantum dot is filled with electrons, the potential is screened, increases in real space, and shrinks in k-space. This will ultimately lead to three equivalent potential pockets, caused by trigonal warping of the bandstructure. The orbital degeneracy in this case is 3. This explains the larger energy cost for adding electron No. 25 in Fig. 4. The addition spectrum of this graphene quantum dot is directly impacted by the underlying bandstructure of bilayer graphene.

In graphene there is a continuous transition from electron to hole occupancy because of the absence of a bandgap. Since the bandgap in the confining barriers is entirely gate-controlled, as is the quantum dot occupancy, the occupation of the quantum dots can also be tuned from electron to hole populations (Banszerus et al., 2020; Tong et al., 2021). The quantum dot shown in Fig. 4 is occupied by electrons and confined by p-n junctions that connect to the p-type leads. This is an unusual confinement potential generally not accessible in semiconductors. In graphene it is also possible to create “standard” tunneling barriers, as in semiconductor systems, where two gates control the tunneling barriers and another gate in the middle (plunger gate) tunes the dot occupancy. This large range of tunability for the dot occupancy as well as for the kind and strength of the tunneling barriers is unique in graphene and enables the realization of complex coupled quantum dot systems (Eich et al., 2018b). On the other hand it is challenging to build charge detectors (Kurzmann et al., 2019a) which rely on basically opaque to slow down electron transport to be within the detector bandwidth. The finite bandgap of bilayer graphene requires relatively wide barriers (≈ 100 nm) to electrically isolate various sample regions.

An interesting situation occurs when a graphene quantum dot is filled with two electrons (see spectrum in Fig. 5). For standard semiconductor quantum dots two electrons can form four spin states: one singlet with its energy lowered by the exchange energy

Fig. 4 Conductance trace through the dot with respect to the applied finger-gate voltage V_{QD} . Adapted from Ref. Garreis R, Knothe A, Tong C, Eich M, Gold C, Watanabe K, Taniguchi T, Fal'ko V, Ihn T, Ensslin K, Kurzmann A (2021) Shell filling and trigonal warping in graphene quantum dots. *Physical Review Letters* 126: 147703.

Fig. 5 Energy levels for two carriers occupying a QD. A finite exchange interaction lowers the spin-triplet states by E_{ex} in energy. A magnetic field splits the spin-triplet states by $g_s\mu_B B$, while a finite perpendicular component of the magnetic field splits mainly the valley-triplet states by $g_v\mu_B B_{\perp}$. Adapted from Ref. Tong C, Kurzmann A, Garreis R, Wister Huang W, Jele S, Eich M, Ginzburg L, Mittag C, Watanabe K, Taniguchi T, Ensslin K, and Ihn T (2022) Pauli blockade of tunable two-electron spin and valley states in graphene quantum dots. *Physical Review Letters* 128: 067702.

with respect to the three triplets. In graphene, the valley degree of freedom plays again an important role. The overall wavefunction has to be anti-symmetric under the exchange of particles. The wavefunction is now composed of three parts: the orbital part, the spin part and the valley part, which also has orbital character but is an additional degree of freedom. This leads to a total of 16 different states. If we assume that the orbital wavefunction is symmetric, i.e. s-like, then the product of spin and valley part of the wavefunction has to be antisymmetric. This leaves as a combination either a valley triplet T_v and spin singlet S_s , or a valley singlet S_v and spin triplet T_s . These are six states in total. The spin states can be split by the Zeeman energy $g_s\mu_B B$. The valley states can be split by the corresponding valley Zeeman effect $g_v\mu_B B_{\perp}$. It turns out that the valley g-factor is one to two orders of magnitude larger than the spin g-factor ($g_s = 2$ in graphene) and can actually be tuned over wide ranges by controlling the size of the dot (Tong et al., 2021). The valley splitting depends only on the perpendicular component of the magnetic field $B_{\perp}$ because it is ultimately an orbital effect.

Fig. 5 summarizes the energy spectrum as it is found in the experiment. By measuring the excited state spectrum using finite bias spectroscopy of the quantum dot in a magnetic field, one can distinguish spin and valley states, for details see Tong et al. (2022). It is found in many experiments that the ground state of a two-carrier quantum dot in graphene is a spin triplet T_s and a valley singlet S_v (Kurzmann et al., 2019b). This interesting finding puts graphene quantum dots aside from all other quantum dots in semiconductors, and also in carbon nanotubes. It opens challenging questions on possible qubit implementations in graphene.

Pauli blockade in graphene double quantum dots

Spin blockade (Ono et al., 2002) has become a versatile tool to investigate spin lifetimes in qubits. The idea is that two electrons occupying two quantum dots (in semiconductors) can have a singlet ground state, if both electrons are in the same dot. If each dot contains one electron then their wave function overlap is strongly reduced and the exchange splitting between singlet and triplet states vanishes. This way spin selection rules arise which lead to blocking of carrier transport even if the process was energetically allowed.

In graphene quantum dots it was shown in the previous section that the two-carrier ground state is a spin triplet T_s and a valley singlet S_v . The spin blocking process described before does not work in this case. Rather another interesting process is likely to occur which is valley blockade, also based on the Pauli exclusion principle but very different in nature and also in the possible mechanisms lifting this blockade situation.

The energy spectrum in Fig. 5 shows the evolution of the two-particle states as a function of magnetic field. Since the valley g-factor is much larger than the spin g-factor, $g_v \gg g_s$, the spin singlet-valley triplet becomes the ground state at sufficiently large perpendicular magnetic fields, here at around 600 mT. In this case one is back to the spin configuration known from semiconductor quantum dots at $B = 0$.

Fig. 6 shows finite bias triangles for both bias directions at finite magnetic field $B = 800$ mT. The horizontal/vertical axes are gate voltages tuning the left/right quantum dot occupation. The configurations (i,j) mark the carrier numbers in the various regions. The triple points, which correspond to the states in the dots being in resonance with each other and with the Fermi levels of the leads,

Fig. 6 Finite-bias triangles $B = 800$ mT with negative (left) and positive (right) source-drain bias. ε is the total energy, and detuning $\delta = \varepsilon_L - \varepsilon_R$ the interdot energy difference. Adapted from Ref. Tong C, Kurzmann A, Garreis R, Wister Huang W, Jele S, Eich M, Ginzburg L, Mittag C, Watanabe K, Taniguchi T, Ensslin K, and Ihn T (2022) Pauli blockade of tunable two-electron spin and valley states in graphene quantum dots. *Physical Review Letters* 128: 067702.

broaden into bias triangles as finite bias is applied across the dots. It is clearly visible in Fig. 6, that the current at the baseline is suppressed for positive voltage bias (right) compared to negative voltage bias (left). This is a signature of Pauli spin blockade. One can also see in the right hand side of Fig. 6, that the current recovers for larger detuning of the energy levels δ , but not to the current level seen on the left hand side of Fig. 6 at the tip of the triangles. The reason for this suppression is valley blockade.

The phase space of possible spin and valley configurations in a two-carrier double quantum dot is much richer than it was known for semiconductor dots. This leads to a more complex energy spectrum with more elaborate selection rules, but also more opportunities. It turns out that a three-electron double quantum dot offers yet more prospects of spin blockade at $B = 0$ but this is beyond the scope of the review.

Spin lifetimes in graphene quantum dots

Spin qubits are among the most promising contenders for a quantum information processor. The reason is that spins usually live long (longer than charges) because they couple little to the environment. The spin decay times T_1 as well as the coherence times T_2 have been measured for a large number of materials and devices, for a review see Stano and Loss (2022). The dominant decoherence mechanisms are hyperfine coupling of electron spins to nuclear spins and spin-orbit coupling. Natural carbon consists of 99% ^{12}C , which has no nuclear spin. The strength of the spin-orbit coupling roughly scales with the size of the atom. With C being element No. 6 in the periodic table, one would expect long spin decay and coherence times in C-based materials in general and for graphene in particular. While there is a lot of experimental data for semiconductor-based spin qubits (Stano and Loss, 2022), the experimental situation is scarce for graphene, mostly because high-quality graphene quantum dots have only become available recently.

The first experiment follows the so-called Elzerman read-out scheme (Elzerman et al., 2004), which has been pioneered for GaAs-based quantum dots. A charge sensor is capacitively coupled to a quantum dot to detect the charge occupation. If the tunneling barriers coupling the quantum dot to its source and drain leads are sufficiently opaque, such that carrier transport through the quantum dot is slow enough to fall into the bandwidth of the detector, then one can measure in a time-resolved way when carriers enter and leave the quantum dot.

The idea of the Elzerman read-out is sketched in the top panels of Fig. 7. Applying a pulsed voltage to the finger gate of the quantum dot (see Fig. 3), one first lowers the quantum dot states below the Fermi levels of source and drain to load one carrier into the dot (load phase). As a finite magnetic field is applied, the Zeeman splitting is larger than the thermal energy kT . During the read phase, the Zeeman-split levels are positioned with respect to Fermi levels of source and drain, such that the lower (upper) state is below (above) the Fermi levels of source and drain. If, during the load phase, a charge carrier was loaded into the higher energy spin state, see upper left panel of Fig. 7, then it may leave the dot to source/drain and is replaced by a carrier occupying the lower spin state. This event is observed by the charge detector, see lower left panel in Fig. 7. Here we assume that the time for the spin to decay from the higher to the lower spin state without leaving the dot is longer than the tunneling times.

The other situation, where the carrier is loaded into the lower spin state is sketched in the top right panel of Fig. 7. In this case the carrier just stays there during the read phase and the detector does not detect any time dependent charging of the dot, see lower right panel of Fig. 7, for details see Gächter et al. (2022).

When increasing the load time, the likelihood for the carrier loaded into the excited states to decay to the ground state is increased. By taking many such measurements as shown in Fig. 7 and changing the load time, one can extract the decay time from

Fig. 7 Top: Three-level pulse scheme applied to the plunger gate. Read-level configuration allowing for single-shot read-out. Bottom: Exemplary traces for a carrier loaded into the spin state which is above (left) or below (right) the Fermi level in the read phase. Adapted from Ref. Gächter LM, Garreis R, Tong C, Josef Ruckriegel M, Kratochwil B, Kornelis de Vries F, Kurzmann A, Watanabe K, Taniguchi T, Ihn T, Ensslin K, Wei Huang W (2022) Single-shot readout in graphene quantum dots. *PRX Quantum* 3: 020343.

the excited to the ground state. We find values of the order $T_1 \approx 50$ ms which compares well with the best results for semiconductor devices (Stano and Loss, 2022). This result is important in view of the prospects of qubit physics and technology in graphene.

Prospects of graphene qubits

Graphene has emerged as a marvelous material with exciting electronic, mechanical and thermal properties. Only during the last 5 years it has become feasible to prepare high-quality quantum devices that are on par with what has been realized in the semiconductor world. The breakthrough occurred when it became possible to define charge carriers by electrostatically defined barriers. In bilayer graphene this is based on a significant bandgap that can be opened by appropriate gate voltages. What seems relatively straight forward today required hard work and technology development by many researchers over many years. Today many graphene quantum dot devices are operated in several research groups that reproducibly show single charge occupation and stable operation as a function of time and other parameters, which is crucial for qubit technologies. First results on long-lived spins have been demonstrated and experiments measuring spin coherence times are just around the corner.

The electronic spectrum of graphene quantum dots has been measured and understood in great detail for single, double and triple charge occupation. In this review we have mostly dealt with arguments based on a single-particle picture to keep the discussion comprehensible. It should be noted, however, that there is a significant spin-valley coupling of the order of 60–80 μeV (Kurzmann et al., 2021; Banszerus et al., 2021) lifting the four-fold degeneracy of the ground state even for one-carrier occupancy. Also the Kondo effect has been observed (Kurzmann et al., 2021) indicating a significantly richer spectrum than for comparable semiconductor systems. These effects will impact future experiments and technological developments for graphene quantum dots.

One of the most important differences between graphene and semiconductors is the valley degree of freedom. While Si also has a valley degree of freedom, it is difficult to control and mostly avoided for qubit operation. For graphene, on the other hand, this valley degree of freedom is entwined with the fact that the primitive unit cell of the honeycomb lattice has two atoms. The valley degree of freedom in graphene is well controlled, understood and its influence on the energy spectrum can be tuned by gate voltages and magnetic fields. The valley degree of freedom profoundly impacts the energy levels of a quantum point contact in a magnetic field. In quantum dots it leads to a dramatic increase of the size of the Hilbert space already for two carrier operation. It has so far unknown consequences for spin decay and coherence times and opens the door for valley qubits, a term used in the larger community for many years but not experimentally realized so far. The prospects here are amazing. In order to have intervalley coupling one requires a scattering event on the scale of the lattice constant, which is very unlikely in smoothly defined confinement potentials. At the same time one has to think about manipulation mechanisms for valley qubits. If valley qubits will really be as long-lived as these arguments suggest, one may consider coupled charge-spin-valley qubit system, where manipulation and coupling is done in one part of parameter space and storage of quantum information in another one.

Two-dimensional materials such as graphene are one atomic layer thin by definition, i.e. much thinner than corresponding semiconductor environments. Given the fact that all nanotechnology to pattern these materials is top-down, involving lithography, etching and gating, the pattern size that can be realized for lateral dimensions is ultimately limited by the vertical dimension.

With hBN an almost perfect insulator exists. One could presumably build an hBN/bilayer graphene/hBN stack with the thickness of a few nm, i.e. much thinner than anything possible with semiconductors. Assuming further, that our lithographic capabilities will improve to prepare for example split-gate geometries on the sub 10 nm scale, one may be able to build quantum devices which are much smaller than today, have much larger confinement energies, can maybe be operated at higher temperatures and may display much stronger coupling between neighboring devices.

The big advantage of semiconductor quantum devices is the availability of wafer-scale processing and compatibility with industrial classical technology. The best graphene devices today, on the other hand, are all build by exfoliation techniques using sticky tape, the same way graphene was originally prepared by Geim and Novoselov. It has been demonstrated that single-layer graphene can be grown by MOCVD (Schmitz et al., 2020) with an electronic quality leading to the observation of the fractional quantum Hall effect. This catalytic self-limiting process typically does not work well to grow bilayer material, a process still to be developed. The high-quality insulator hBN prepared by K. Watanabe and T. Taniguchi and used by most graphene groups also exists only in flakes. Efforts are underway to prepare large area hBN, which might have consequences way beyond graphene, including other two-dimensional materials such as TMDs, and maybe even standard semiconductors. It is clear that from the material side there are many obstacles to be overcome in order to have large area/wafer scale and high quality heterostructures of two-dimensional materials.

The connection to other two-dimensional materials offers new opportunities. Transition-metal dichalcogenides (TMDs) are electronically of not as high quality presently as graphene. This might change, however, and then two-dimensional materials with a bandgap comparable to standard semiconductors will be available. Heterostructures of TMDs with graphene can be used to induce spin-orbit coupling, which is very strong in TMDs, into graphene (Wang et al., 2016). This valuable experimental approach has not yet been used to design quantum device in graphene. The bandstructure in graphene can also be modified by twisting the graphene layers, culminating in the discovery of superconductivity (Cao et al., 2018). First devices have been built on this platform (de Vries et al., 2021; Rodan-Legrain et al., 2021; Portolés et al., 2022). Overall, the world of two-dimensional materials offers unique opportunities to build hybrid quantum devices of all facets, mostly in view of new physical discoveries, but also with the prospect to impact qubit technologies in the future.

Abstract

The effect of a plane terminating the crystal is presented through the modifications introduced in the atomic and electronic structure of the solid. Reconstruction and relaxation of the surface layer, and the subsequent appearance of new electronic states are discussed, reporting significant examples from semiconductors. The formation of an interface is then introduced, with a spotlight on the solid-liquid interface. In this case, under definite experimental conditions surface structures like those observed in ultra-high vacuum are obtained, thus moving the investigation from clean surfaces towards real-world environment.

Key points

- Clean surfaces are obtained in Ultra High Vacuum (UHV) conditions, by several preparation methods (cleavage, ion bombardment and annealing, high-temperature annealing, molecular beam epitaxy, etc.).
- When the surface is prepared, two deviations from the ideal case are possible: relaxation and reconstruction.
- The structural variations associated with reconstruction have important consequences on the electric properties of the surface.
- New electronic states appear, localized at the surface layer with energies in the forbidden gap: these are “surface states”.
- In semiconductors, the presence of surface states—especially when localized in the bulk gap- modify many of the sample properties significantly.
- The position of the Fermi level at the surface is altered by accumulation of charge into surface states, introducing a “band bending”.
- Interfaces are the regions connecting two different physical systems.
- When the interface forms and thermal equilibrium is reached, the Fermi levels of the two sides line up. This alignment produces a charge redistribution to preserve the overall neutrality of the system, changing the electrical properties of the contact zone.
- The presence of surface states at the interface (interface states) has important consequences on the electrical behavior of the system.
- A heterojunction is a particular interface, created between two different semiconductors.
- Beyond clean surfaces in UHV, also surfaces immersed in a liquid reconstruct.

Nomenclature

k	Wave vector (cm^{-1})
L_D	Debye length (cm)

[☆]Change History: November 2022. C Goletti has been involved in preparing the update. Only main text and references have been updated.

ΔE_c	Conduction band discontinuity (eV)
ΔE_v	Valence band discontinuity (eV)
ρ^{local}	Local density of states (states atom ⁻¹ eV ⁻¹)
ρ^{tot}	Total density of states (states atom ⁻¹ eV ⁻¹)
Φ	Work function (eV)
Φ_{SB}	Schottky barrier (eV)
χ	Electron affinity (eV)
ψ	Wave function

Introduction

The presence of the surface modifies significantly the atomic and electronic structure of the first few layers of the solid. Since some of the properties of the solid are to some extent properties of its surface (e.g., the work function, the photoelectric threshold, chemisorption and physisorption, conductivity in the surface channel(s), optical reflectance, and the scattering of electrons, ions, and atoms by the solid), a detailed knowledge of the surface is important for solid-state physics and chemistry as well as for materials science and technical applications.

In this article, the discussion is limited to the so-called “clean surfaces,” or surfaces that are atomically clean (i.e., with a controlled chemical composition) and crystallographically well defined. “Real surfaces” (i.e., surfaces with unspecified chemical impurities, crystallographic defects, macroscopic faults, etc.) are considered only occasionally.

Clean surfaces are obtained in ultrahigh vacuum (UHV) conditions (10^{-10} Torr or better) by cleavage, ion bombardment and annealing (IBA), high-temperature annealing, molecular beam epitaxy (MBE), etc. Conversely, real surfaces are obtained and handled at ordinary pressures, mechanically ground, chemically etched, etc., and their properties often depend upon the way of preparation.

This article discusses the surface reconstruction and relaxation, electronic surface states, examples of reconstruction of relevant semiconductor surfaces and interfaces.

Surface reconstruction and relaxation

The structure of an “ideal surface” is that of a half crystal obtained by dividing the crystal in two halves with a lattice plane as a boundary, removing all atoms on one side and leaving the other atoms in their original positions. An ideal surface is then characterized by the Miller indices of the boundary plane.

It should be considered, however, that the atoms in the ideal surface plane experience a force different from that of their partners in the bulk. Moreover, they have a larger freedom of movement so that some rearrangement takes place due to the reduction of the free energy of the surface. Two deviations from the ideal surface are possible: relaxation and reconstruction. Relaxation consists of a rigid displacement of all the atoms of the surface plane (in general, perpendicularly to it) that leaves unaltered the translational symmetry of the surface. On the contrary, reconstruction is a displacement of individual atoms that changes the translational symmetry in the surface plane.

The two situations are schematically shown in Fig. 1 (where it is assumed that the planes are stacked on top of each other to obtain the three-dimensional (3D) crystal). It is seen that in case (b), which represents relaxation, the surface unit cell is still a square of side a , while in cases (c), (d) and (e), which represent reconstruction, the surface unit cell is a rectangle of sides a and $2a$. In Wood’s notations, these last reconstructions are called 2×1 . It is seen that Wood notations do not univocally characterize the

Fig. 1 Schematic representation of a surface: (a) ideal surface, (b) relaxed surface, (c), (d), and (e) reconstructed surfaces (simplified examples of buckling, dimerization, and missing row models).

surface: they only give the symmetry of the reconstruction. As such, they are directly obtained from the LEED (low energy electron diffraction) patterns. The experimental determination of the actual coordinates of the atoms of the first few layers (that would completely characterize the reconstructed surface) is a very complex problem that may require the use of various techniques and the comparison with theoretical models. Among the most common techniques used for this purpose are: dynamical LEED, STM (scanning tunneling microscopy), ARUPS (angle-resolved ultraviolet photoemission), inverse photoemission, optical reflectance with polarized light, high-energy electron diffraction, elastic and inelastic scattering of atoms, ions, and electrons, etc. Energies associated with reconstruction are $\sim 10^{-2}$ eV/atom⁻¹ for metals and $\sim 10^{-1}$ eV/atom⁻¹ for semiconductors. Metals are then seldom reconstructed, while semiconductors are very often so. In metals, in fact, electrons are delocalized so that the free energy does not depend much on the position of the single atoms. The opposite is true in semiconductors where directional bonding is significant. Tables 1 and 2 list a few examples of reconstruction of metals and semiconductors. It is seen that, for a given surface, various reconstructions are possible, depending upon the method by which the surface is obtained (shown in the last column). In a few instances, reversible transformations between two phases of reconstruction have been observed as a function of temperature. On the other hand, impurities and defects may stabilize some phases. The tables show clearly that reconstruction is a problem of extreme variety and complexity, as well as of the greatest interest. Up to now, a theory that explains the occurrence of the various types of reconstruction is not available from first principles. Guidelines and heuristic models are discussed in the section "Examples of reconstruction of relevant semiconductor surfaces."

Table 1 Surface structure of (some) metals.

<i>Metal</i>	<i>Face</i>	<i>Reconstruction</i>	<i>Model</i>	<i>Preparation and remarks</i>
Ag	(1 0 0)	1×1	Relaxation	Epitaxial film on MgO. 1×1 stable for $T < 773$ K

ann. = annealing; IBA = ion bombardment + annealing; MBE = molecular beam epitaxy.

Electronic surface states

The structural variations associated with reconstruction have important consequences on the electronic properties of the surface. Regardless of this, however, the reduction of the translational invariance caused by the surface is enough to introduce additional levels in the electronic structure of the solid. This was shown, for a Kronig-Penney potential, by I. Tamm in 1932 and extended to a more realistic case by W. Shockley in 1939. A 1D potential with a surface at $z = 0$ is shown schematically in Fig. 2a. Inside the solid ($z < 0$) the wave function is given, according to the Bloch theorem, by

$$\Psi(z, t) = u_k(z) \exp[i(kz - \omega t)] \quad (1)$$

where $u_k(z)$ is a function with the same periodicity of the lattice, $k = 2\pi/\lambda$ is the wave number, and $E = \hbar\omega$ is the energy of the electron. For an unbound lattice ($-\infty < z < +\infty$), k must be a real number so that Eq. (1) represents a wave propagating along z . Imaginary values of k are discarded because the wave function cannot be normalized. Since the energy is a function of k , real (imaginary) values of k correspond to allowed (forbidden) bands. In the presence of a surface, however, imaginary values of k cannot be discarded since now, the wave function can be normalized and states localized at the surface, with energies in the forbidden gaps, become possible. If it is assumed that $k = i\mu$ (with μ real), the spatial part of the wave function can be written (for $z < 0$) as

$$\psi_\mu(z) = u_\mu(z) e^{-\mu z} \quad (2)$$

When $\mu < 0$, the wave function can be matched, at the surface, to that appropriate for $z > 0$ (a decaying exponential if the potential is given by a step function). This is shown in Fig. 2b that represents schematically a state localized at the surface with energy in the forbidden gap. Such a state is called a “surface state.” The matching, however, can also be done when k is real, giving rise to the state shown in Fig. 2c that represents a bulk electron scattered at the surface. In three dimensions, the translational symmetry is preserved on the surface plane so that the surface state is now represented by a Bloch wave propagating along the surface with wave vector $k_\parallel$; damped on both sides of the surface as in the 1D example. In this case, however, the energy of the surface state does not necessarily fall into the forbidden gaps because of the energy (kinetic and potential) associated to the motion along the surface.

When the degeneracy of the surface state with the bulk bands is not limited to energy but extends to k -values, the state is called a “resonant state.” A 1D example is shown schematically in Fig. 2d. In a naïve picture, such a resonant state corresponds to a bulk electron that is scattered at the surface, though dwelling there for some time. In order to present the correlation between surface and bulk states, it is customary to project the bulk bands on the surface Brillouin zone and plot the surface bands there. This is done for unreconstructed Si(111) in Fig. 3. Surface states are represented by dotted lines, surface resonances by full lines, while projected bulk bands are shown as hatched regions.

When the surface is reconstructed, the calculation of the bands is more difficult and can be done only on the basis of a model. A common procedure is to pile up a number of crystallographic planes where atoms are displaced from their ideal positions according to a given model of reconstruction. The slab should be large enough (10–20 layers) so that in the interior, the structure of the bulk is resumed. Each slab exposes two surfaces. The slabs are then arranged periodically with spacing (between each two) large enough to avoid a sizable perturbation. This fictitious periodic structure allows the use of the theorems of the 3D band theory. The results are usually presented in terms of the so called “local density of states.” As it is known, the “total density of states” $\rho^{\text{tot}}(E)$ gives the number of states present in a unit energy range around E :

$$\rho^{\text{tot}}(E) = \sum_i \delta(E - E_i) \quad (3)$$

Fig. 2 Schematic representation of a surface in a 1D model: (a) potential energy of an electron, (b) wave function for a surface state with energy in the gap, (c) bulk electron scattered at the surface, and (d) surface resonant state.

where δ is the Dirac function and the sum runs over the energy states E_i .

In turn, the local density of states is defined as:

$$\rho^{\text{local}}(x, y, z; E) = \sum_i |\Psi_i(x, y, z)|^2 \delta(E - E_i) \quad (4)$$

that is, each state is weighed with the probability of finding an electron at x, y, z . Fig. 4 shows the local density of states for the ideal surface Si(1 1 1) 1×1 . The figure clearly shows the presence of unsaturated bonds (dangling bonds, DB) on atoms of the first layer.

An important development for calculating the structural and electronic properties of a surface came from the application of the so-called Car-Parrinello method that consists of simulating the dynamical evolution of a reduced set of atoms (~ 100), starting from an initial configuration that can as well be the ideal surface (Car and Parrinello, 1985). For each configuration, the electronic energy is calculated and, through the Hellman-Feynman theorem of quantum mechanics, the force on the single atoms is determined and so is the dynamical evolution of the system.

Eventually, a stable configuration is reached that corresponds to the reconstructed surface. This “ab initio” calculation requires, however, a high computational power and some “educated guesses,” especially if the reconstruction is not that of thermodynamical equilibrium.

In metals, one-electron theories are generally inadequate, and calculations must be done on the basis of the many-body theory. A model that has given reliable results for the work function of several metals is the so-called “jellium” (Lang and Kohn, 1970), which assumes that the electrons form a gas of negatively charged particles neutralized by a continuous distribution of fixed positive charge that goes abruptly to zero at the surface. Fig. 5 shows the electron density distribution near the surface for two cases representative of

Fig. 3 Bulk bands projected into the surface Brillouin zone for the ideal (un-reconstructed) surface of Si(1 1 1). Bulk bands are hatched; surface states are shown with dotted lines; surface resonances with full lines. The surface Brillouin zone is shown on the right. After Schlüter M and Cohen ML (1978) *Physical Review B* 17: 716.

Fig. 4 Charge density contours in the (110) plane (perpendicular to the (1 1 1) surface) for the un-reconstructed (ideal) surface of Si(1 1 1). The dangling bonds protruding into vacuum are clearly visible on the atoms of the surface layer. After Schlüter M, Chelikowsky JR, Louie GS and Cohen ML (1975) *Physical Review B* 12: 4200.

Fig. 5 Surface charge density for the jellium model of a metal, plotted for two values of the electron densities. The radius r_s (in atomic units) is that of the sphere that contains one electron. $r_s = 2, 5$ correspond approximately to the cases of Al and Cs, respectively. After Lang ND and Kohn W (1970) Theory of metal surfaces: Charge density and surface energy. *Physical Review B* 1: 4555.

Al (dashed line) and of K (continuous line). Electrons protrude from the surface giving rise to an electric dipole directed inwards, which reduces the work function. Characteristic oscillations of the electron density (Friedel oscillations) should be noticed.

A further peculiarity of metals is that the major contribution to the surface barrier comes from the image force of electrostatics. The potential energy is then, at a large distance from the surface, Coulomb-like. If the electron energy corresponds to a gap, the electron cannot penetrate the solid and remains confined in a sort of a well that extends from $z = 0$ to the Coulomb barrier. In such a well, quantized levels called “image states” exist (Echenique et al., 1985). Each state is characterized by an integer quantum number, $n \geq 1$. In this scheme, the Shockley (or Tamm) states are those with $n = 0$.

The states discussed so far are called “intrinsic surface states” and can be observed only on clean surfaces. On real surfaces, electronic states associated with mesoscopic defects such as steps, kinks, islands, terraces, and pits, or with surface impurities are also present. Such states are called “extrinsic surface states” and may modify the properties of technical surfaces.

In semiconductors, the presence of surface states (both intrinsic and extrinsic), especially when localized in the gap, modifies many of the properties of the sample significantly. The accumulation of charge into surface states creates a macroscopic potential that alters the position of the Fermi level at the surface and introduces a “band bending” that extends for a length of the order of the Debye length defined as L_D

$$L_D = \sqrt{\frac{\epsilon_b \epsilon_0 kT}{e^2 (n_b + p_b)}} \quad (5)$$

where ϵ_b (ϵ_0) is the dielectric constant and n_b, p_b the densities of negative and positive carriers in the bulk. L_D spans from a fraction of an Å at metal densities to a fraction of a mm in large gap semiconductors. Such a band bending bears a great importance on many functions of the metal oxide semiconductor (MOS), Schottky barrier, and heterostructure devices.

Examples of reconstruction of relevant semiconductor surfaces

A few examples of reconstruction of relevant surfaces of semiconductors and some of their associated electronic properties are given below. An outline of the basic experimental evidence is also presented for each surface.

Covalent or partially ionic semiconductors such as C (diamond), Si, Ge, GaAs, GaP, GaSb, InAs, InP, and InSb, crystallize in the diamond, zinc blende (or wurtzite) structures in which each atom is tetrahedrally coordinated with four neighbors. The chemical bond is essentially of the directional sp^3 type. The presence of the surface introduces a number of unsaturated bonds called dangling bonds (DBs) that play a great role in reconstruction.

Since the energy associated with sp^3 bonds is rather high, the atoms on the surface tend to rearrange in order to reduce the number of DBs. This can be done in a number of ways: dimerization, formation of adatoms (i.e., atoms that have left their ordinary position to sit in the interstice on top of three atoms), p-bonding, etc. It should be observed in this respect that the sp^3 bond is easily deformable, in the sense that little energy is required to change the angles among the bonds. Reconstruction takes advantage of this flexibility, allowing several different structures to be present even on the same surface.

Si(100) 2×1

The ideal (1 0 0) face exposes two DBs per surface atom and is then highly unstable. Dimerization is a process that produces the 2×1 reconstruction usually observed. The 2×1 reconstructed surface is shown schematically in Fig. 6: (a) in top view and (b), (c) in side view. The dimers are symmetric in (b) and asymmetric (buckled) in (c). A small buckling is believed to stabilize the surface. The saturation of the DB cannot be complete so that other types of reconstruction are observed, namely $p(2 \times 2)$ and $c(4 \times 2)$ that occur on $\approx 5\%$ of the surface. Two STM pictures that show the three types of reconstruction on the same surface are presented in Fig. 7: in the upper picture dimers are seen most distinctly in rows 7, 1, 13 while the $p(2 \times 2)$ reconstruction is seen in rows 14–15. On the other hand, the $c(4 \times 2)$ reconstruction is seen in rows 2–3 of the lower picture (Tromp et al., 1985).

Si(1 1 1) 2×1

The (1 1 1) face is the cleavage plane of Si and exposes one DB per surface atom. The 2×1 reconstruction is observed after cleavage at $T < 550$ K at which temperature it transforms irreversibly into the more stable 7×7 structure. The electronic structure consists of two bands (one full and one empty) separated by a gap of ~ 0.5 eV, from which optical transitions are observed (Chiarotti et al., 1971; Chiaradia et al., 1984). The opening of the gap is probably the process that stabilizes the surface.

Several models have been proposed for this surface. The only one that satisfies the various experimental findings is that proposed in 1981 by K C Pandey, which consists of π -bonded chains along [110] directions (Pandey, 1981). The model is shown in Fig. 8 in top and side views. It is seen that in order to create the chains some bonds should be broken. This, however, can be done almost adiabatically (with negligible activation energy) as can be seen from Fig. 9, where the local density of states is plotted for various configurations starting from a slightly buckled (almost ideal) surface.

The chain model explains, among others, the following experimental results: (1) the great anisotropy of optical transitions that occur only if the electric vector lies on one of the [1 1 0] directions (Chiaradia et al., 1984) and (2) the strong dispersion of the occupied states observed in photoemission (Himpsel et al., 1981). The model has been subsequently verified directly by STM (Feenstra et al., 1986). A small buckling along the chain (Fig. 8c) is necessary to explain the relatively large optical gap.

Fig. 6 Stick and ball model of the surface of Si(1 0 0) reconstructed 2×1 through dimerization: (a) top view. The 1×1 unit cell (hatched, basis vectors a , b) and the 2×1 cell (basis vectors A , B) are shown; (b) side view; (c) side view with buckled dimers.

Fig. 7 STM pictures of the Si(1 0 0) 2×1 surface. The photographs show locally $p(2 \times 2)$ reconstruction (rows 14, 15 in the upper picture) and $c(4 \times 2)$ reconstruction (rows 2, 3 in the lower picture). From Tromp RM, Hamers RJ and Demuth JE (1985) Si(001) dimer structure observed with scanning tunneling microscopy. *Physical Review Letters* **55**: 1303.

Fig. 8 Stick and ball model of the Si(1 1 1) 2×1 surface, according to the π -bonded chain reconstruction: (a) top view; (b) side view; and (c) side view for a buckled chain.

Fig. 9 Theoretical contour plots of charge density in the (1 1 0) plane of Si(1 1 1)2 $\times$ 1: (a) for a slightly buckled (nearly ideal) surface; (b) for an intermediate geometry; and (c) for the chain model of Fig. 8. After Northrup JE and Cohen ML (1982) *Physical Review Letters* **49**: 1349.

Si(1 1 1)7 $\times$ 7

As already mentioned, this is the equilibrium reconstruction of the (1 1 1) face. The elementary cell contains 49 atoms in the uppermost plane. It has then a complex structure that resisted, for at least two decades, all attempts at theoretical explanation.

By combining accurate electron diffraction at high energies (to avoid multiple scattering), STM pictures (Binnig et al., 1983), and theoretical considerations, K. Takayanagi and collaborators proposed in 1985 the reconstruction model shown in Fig. 10 (Takayanagi et al., 1985). The elementary cell is a rhomb with two nonequivalent halves and four vacancies at the corners. Dimers can be seen along the sides and the shorter diagonal. 12 adatoms and 6 so-called “rest atoms” (i.e., atoms that have maintained their original positions) are also visible. A stacking fault is present in the left half of the elementary cell. The model is then called DAS (dimers-adatom-stacking fault) and is universally accepted. The number of DB (which were 49 in the unreconstructed cell) has now been reduced to 19 (12 on the adatoms, 6 on the rest atoms, 1 in the vacancy). A similar 5 $\times$ 5 structure (with 6 adatoms, 2 rest atoms, and 4 corner vacancies) is seen in surfaces prepared by MBE and is often associated with the more common 7 $\times$ 7.

From the electronic point of view, the 7 $\times$ 7 structure has a metallic character as shown by photoemission and by the absence of optical transitions in the gap.

The distribution of surface states is shown in Fig. 11 where data of photoemission spectroscopy (left curve) and inverse photoemission spectroscopy (right curve) are plotted as a function of energy. The figure shows clearly that there is a continuous distribution of states across the gap, giving rise to the metallic conductivity of the surface.

Fig. 10 Structure of the Si(1 1 1)7 $\times$ 7 surface according to the DAS model: (a) top view; (b) side view. Notice the different positions of the lower neighbors of the rest atoms in the left and right half of the elementary cell, caused by the presence of the stacking fault.

Fig. 11 Schematic distribution of occupied and empty surface states as obtained by photoemission spectroscopy that detects occupied states (left curve) and inverse photoemission that detects empty states (right curve). The energy scale has been referred to the Fermi level (E_F) position.

Fig. 12 Idealized band structure for a topological insulator. The Fermi level falls within the bulk band gap which is traversed by topologically-protected surface states, brought down from the conduction band and raised from the valence band. By A13ean - Own work, CC BY-SA 3.0, <https://commons.wikimedia.org/w/index.php?curid=11101461>.

A completely different example are the so called Topological Insulators (as for example α -Sn(001), or bismuth and antimony chalcogenide based materials (Bi_2Se_3 , Bi_2Te_3 , Sb_2Te_3 , $\text{Bi}_{1-x}\text{Sb}_x$, $\text{Bi}_{1.1}\text{Sb}_{0.9}\text{Te}_2\text{S}$)) in which there are no broken bonds at the surface and the metallic conductivity arises from a shearing deformation that maintains the local topology at the surface (Hasan and Kane, 2010).

From the theoretical point of view, the conductivity is due to a crossed or inverted gap states. In the simplified model shown in Fig. 12, states of the conduction band and valence band coexist at the Fermi level thus giving rise to conductivity.

Interfaces

The interface is the region that connects two different physical systems, for example, a metal and a semiconductor (Schottky barrier), two different semiconductors (heterojunction) and, in an extended sense, the surface itself, which defines the boundary between the solid and the vacuum (or a different environment, as a liquid).

When the interface forms and thermal equilibrium is reached, the Fermi levels of the two sides line up. This alignment produces a charge redistribution to preserve the overall neutrality of the system, changing the electrical properties of the contact zone.

If two metals come into contact, the difference between the respective work functions results in a flow of electrons from the metal with lower work function Φ_1 into the metal with higher work function Φ_2 . A contact potential difference $\Delta = (\Phi_2 - \Phi_1)/e$ develops between the metals (Volta effect), and a dipole layer appears at the interface. Due to the high charge density in metals, the thickness of the interface region is only a fraction of an angstrom.

If the junction connects a metal and a semiconductor, the Fermi level alignment in both materials results in the band scheme of Fig. 13 where the band structures are shown in equilibrium: (a) before and (b) after the contact. An electron moving from the metal to the semiconductor (or vice versa) experiences a barrier (Schottky barrier, Φ_{SB}) given by

$$\Phi_{SB} = \Phi - \chi \quad (6)$$

where χ is the electron affinity of the semiconductor.

The space charge layer in the semiconductor has a much larger width than in the metal because of the difference of carrier densities and screening lengths (for the definition of Debye screening length see the section "Examples of reconstruction of relevant semiconductor surfaces", Eq. (5)).

In Fig. 14, the experimental values of the Schottky barrier for different metals deposited onto the Si(1 1 1) 2×1 surface are shown. Though the general trend of Eq. (6) is maintained, it is apparent that the simple theory outlined above (dotted line) is inadequate to fit the experiments. The qualitative explanation is that in deriving Eq. (6), the presence of electronic surface states at the interface (interface states) has been neglected. If their density is sufficiently large, they pin the Fermi level at the surface of the semiconductor, making the Schottky barrier independent of the work function of the metal (dashdotted line in Fig. 14). The experimental situation is intermediate between the two hypotheses (i.e., absence of interface states and complete pinning of the Fermi level).

The nature of the interface states has been the subject of extended research. An important advancement came from the introduction of the so-called metal-induced gap states (MIGS) (Heine, 1965). Consider again Fig. 2c of the section "Electronic surface states," where the scattering of a bulk electron at the surface is outlined. If the electron at the metal side of the junction has an energy corresponding to the semiconductor gap, it cannot propagate for $z > 0$. A situation similar to that of Fig. 2c is then a reasonable approximation for the interface wave function: the electronic charge spills into the semiconductor giving rise to a density of states localized at the interface in the semiconductor side (MIGS).

On the other hand, extrinsic states due to defects, mismatching, impurities, and structural changes induced by interface chemical reactions have the same general effect as MIGS. A comprehensive theory of the electronic structure of interfaces is at present not available.

Fig. 13 Band scheme of a metal-semiconductor (n -type) system: (a) before the contact is established; (b) in equilibrium after the contact. Φ_M , Φ_{SC} are the work functions of the metal (semiconductor), χ_{sc} the electron affinity of the semiconductor. Φ_{SB} the Schottky barrier height, and eV_s the band bending at the surface.

Fig. 14 Experimental values of Schottky barriers for several metals on top of Si(1 1 1) 2×1 . The lines represent (a) the Schottky behavior given by Eq. (6) (dotted) and (b) the case of complete pinning of Fermi level at the surface (Bardeen behavior, dash-dotted). After Mönch W (1986) Festkörperprobleme. In: *Advances in Solid State Physics*, vol. 26. Braunschweig: Vieweg.

Fig. 15 Band scheme of a heterojunction: (a) when the materials are not in contact, (b) after the contact is established, but before equilibrium (Fermi levels not aligned), (c) in equilibrium, (d) in equilibrium, when interface states are present.

If the interface is created between two different semiconductors, it is called a heterojunction. The alignment of the Fermi levels on both sides determines the band scheme shown in Fig. 15. The difference between the forbidden gaps of the two semiconductors is distributed between the valence-band discontinuity (ΔE_v) and the conduction-band discontinuity (ΔE_c). Moreover, band bending (eV_1 and eV_2) occurs at the two sides of the interface. Given their great influence on carrier transport, they are the important parameters determining the performance of the interface and play a central role in the behavior of real heterojunction devices (diodes, solar cells, photodetectors, lasers, quantum devices, etc.).

The presence of electronic states at the interface modifies the distribution of charge producing the situation schematically presented in Fig. 15d. Such states originate, in analogy to MIGS, from the tailing of the semiconductor wave function in the forbidden gaps.

In the ideal heterojunction, the two materials have the same (or slightly different) lattice parameters so that there is little strain at the interface, and the materials maintain their original properties up to the abrupt junction. If the lattice parameters are different, strain results at the junction, with the formation of dislocations, defects, and disorder. Sizable interdiffusion and chemical reactions may also occur. Such defects give rise to extrinsic electron states.

Three significant examples are given below:

1. The interface resulting after growth of GaAs (lattice parameter $a = 5.6531 \text{ \AA}$) onto AlAs ($a = 5.6622 \text{ \AA}$) is a representative example of a nearly ideal heterojunction between materials with a very small lattice mismatch ($\Delta a/a = 0.5\%$). The resulting interface is atomically abrupt, with a very low number of defect states.
2. The interface between Ge ($a = 5.6578 \text{ \AA}$) and Si ($a = 5.4307 \text{ \AA}$) presents a lattice mismatch of 4%, too large to be simply accommodated by a strained layer. The interface is then characterized by intermixing, with the formation of a Ge—Si alloy.
3. In the junction between Ge ($a = 5.6578 \text{ \AA}$) and GaAs ($a = 5.6531 \text{ \AA}$), the mismatch is extremely favorable (about 8×10^{-4}). Nevertheless, the chemistry of materials, that is, the high chemical affinity of Ge, Ga, and As produces a great complexity of the interface composition, with possible effects on doping. Ge acts as a donor or an acceptor in bulk GaAs, while Ga and As are, respectively, an acceptor or a donor when the Ge atom is substituted.

Heterojunctions and heterostructures (i.e., the sequence of a high number of heterojunctions, as in a superlattice) are usually grown by MBE or metalorganic chemical vapor deposition (MOCVD). These epitaxial techniques allow the production of graded junctions that are important in many semiconductor devices.

Surfaces in real-world environment

The investigation of surfaces immersed in liquids is remarkably less common with respect to the case of surfaces in UHV. However, important technologies are based on processes that occur at the solid/liquid interface, like electro-catalysis, grafting, biofunctionalization of surfaces, electrodeposition and electro etching of metals down to the nanometer scale. Also biophysical and biochemical systems are commonly prepared and studied in aqueous solutions, and processes of high scientific relevance take place at the

contact with the liquid ambient. These facts urge to bridge the gap between the research on surfaces under ideal conditions (as in UHV) and on surfaces under realistic conditions.

Although the cleanliness conditions (under preparation protocols for both the surface and the liquid) allow the maintenance of the clean phase for a surface in solution during the time necessary for experiments, only a few spectroscopies and methods can penetrate a thin layer of liquid and reach the solid/liquid interface for in situ study. Photon-based probes [as optical techniques -e.g. Reflectance Anisotropy spectroscopy (RAS)- or X-ray diffraction methods] do not suffer this limitation, provided that the liquid is not absorbing in the selected photon energy range, as already demonstrated in pristine electroreflectance measurements. Also scanning probes (AFM and STM, the latter after the metal tip has been insulated by an appropriate coating) allow the investigation of immersed surfaces, and real space images of their structure can be acquired with atomic resolution.

It has thus been shown that single crystalline surfaces of metals in liquid exhibit clean phases as in UHV (Fig. 16a) (Wilms et al., 1999). Furthermore, in electrolytes the adsorption/desorption of ions -effectively assisted by appropriate voltage values applied to the surface with respect to solution- can induce the reconstruction of the surface, determining differently ordered layers (Fig. 16b). Similarly, if different species (ions and/or molecules) coexist within the solution, competing for adsorption sites on the surface, the choice of the potential applied to the sample can tune processes otherwise not possible in UHV (as the electro-compression/-decompression of iodide layers on Cu(100) and Cu(111)). Electrochemical reactions at the solid-liquid interface can be monitored in real time, as shown in Fig. 17, where the interaction of chloride ions with a (110) copper surface in hydrochloric acid solution is followed in situ by RAS and STM (Goletti et al., 2015).

Conclusion

The termination of a crystal with a cutting plane, producing what we call *the surface*, is not merely the introduction of a geometrical boundary, but creates a new fascinating world having peculiar structural and electronic properties with respect to the underlying bulk. Any surface is then an *interface*, that is a region separating (with a quite abrupt discontinuity) the solid and a different phase in contact (solid, liquid, gaseous), associated to important physical and chemical processes in sensors, piezoelectric and optoelectronic devices, fuel cells, catalysts, solar cells, nanotechnology, etc.. Surfaces are the *skin* of the materials, the interface with the external world, and consequently the place where fundamental phenomena happen. Clean surfaces in UHV have represented the playground where nearly all the computational methods and the experimental techniques developed for about 50 years in solid state physics have been applied. In the last years new (sometimes revolutionary) topics have appeared, confirming that the physico-chemical properties of surfaces and interfaces govern the interfacial transport of light, excitons, electrons, ions, energy as well as the transduction of electrons into the molecular language of cells. To mention some important examples: (i) topological materials, with surfaces that are robust against any perturbations as long as respecting symmetry of the system (Moore, 2010); (ii) graphene and 2D van der Waals (vdW) layered semiconductors, truly surface materials providing applications in numerous quantum mechanical devices (Duong et al., 2017); (iii) surfaces of wide bandgap and metal oxide materials (SiC, GaN, Ga₂O₃, ZnO, diamond, TiO₂), with an overwhelming range of physical and chemical applications (Diebold et al., 2010); (iv) biological and organic interfaces, leading to the new challenges of the organic bioelectronics emerging field (Fahlman et al., 2019); (v) superhydrophobic surfaces, whose investigation has become a hot topic for its outstanding properties and wide application values in recent years (Jiaqiang et al., 2018).

Fig. 16 Panel (a) Atomic structure of clean Cu(111) in 5 mM H₂SO₄ (2.7 nm × 2.7 nm, $I_t = 51$ nA, $U_{bias} = 286$ mV). The potential applied to the surface is -800 mV vs. Hg/Hg₂SO₄. Panel (b) Adsorbate structure on Cu(111) in the same solution, when the applied voltage is -440 mV vs. Hg/Hg₂SO₄ (9.6 nm × 9.6 nm, $I_t = 51$ nA, $U_{bias} = 195$ mV). The small bright dots in panel b represent individual sulfate or bisulfate anions; the long range intensity modulation indicates a Moire superstructure. Abstract

Graphene is a one-atomic thickness carbon sheet with a hexagonal lattice structure. The low-energy electronic states of graphene near the Fermi energy are well-described by massless Dirac equation, which gives conical energy dispersion and nontrivial Berry phase. The analysis of Zak phase (known also as $\mathbb{Z}_2$ Berry phase or one-dimensional version of Berry phase) clarifies the existence of topological edge states at graphene zigzag edges. In this chapter, we provide an overview of electronic and topological properties of graphene. The analytic properties of energy spectrum for graphene nanoribbons and carbon nanotubes are also presented.

Key points

- Electronic and topological properties of graphene are presented.
- Low-energy electronic states of graphene are well-described by massless Dirac equation, resulting in the linear energy dispersion with Berry phase π .
- Analysis of Zak phase on electronic wave functions of graphene predicts the existence of graphene edge states.
- Analytic properties of energy spectrum for graphene nanoribbons are presented.
- Analytic properties of energy spectrum for carbon nanotubes are presented.

Introduction

Graphene is a one-atomic thickness monoatomic carbon sheet, which has the hexagonal lattice structure (Geim and Novoselov, 2007; Novoselov et al., 2004, 2005; Zhang et al., 2005). Since carbon atoms in graphene form sp^2 hybridization, each carbon atom provides one π -electron which itinerates over the graphene. The π -electron of sp^2 carbon atoms governs the electronic properties of graphene near the Fermi energy (Aoki and Dresselhaus, 2014; Foa Torres et al., 2014; Katsnelson, 2012; Neto et al., 2009; Saito et al., 1998; Wallace, 1947). Owing to the honeycomb crystal structure of graphene, there are two inequivalent sublattices (two geometrically nonequivalent carbon atoms) in the unit cell, which work as the internal degree of freedom for electron wave functions. In particular, the motion of electrons in graphene near the Fermi energy is well described by the massless Dirac equation (Weyl equation), which can be obtained from tight-binding model for π -electrons by expanding the wave function at the Fermi points (Ajiki and Ando, 1993; Ando, 2005; Ando et al., 1998). At these points, graphene has the conical energy dispersion, i.e., Dirac cone, where the valence and conduction bands conically touch with each other. Since the wave function at Dirac cone has the same form with the eigenfunction of a spin in magnetic monopole field, it accompanies with the nontrivial topological phase, i.e., Berry phase (Berry, 1984).

Further topological aspect can also be observed by inspecting the edge effect on electronic properties of graphene. The presence of edges in graphene has strong implications for the low-energy spectrum of the π -electrons (Fujita et al., 1996; Nakada et al., 1996; Wakabayashi et al., 1999). There are two basic edge shapes, *armchair* and *zigzag*, which determine the properties of graphene nanoribbons (GNRs). It has been shown that nanoribbons with zigzag edges (zigzag graphene nanoribbons, ZGNRs) possess localized edge states with energies close to the Fermi level (Fujita et al., 1996; Nakada et al., 1996; Wakabayashi et al., 1999). In contrast, edge states are absent for nanoribbons with armchair edges (armchair graphene nanoribbons, AGNRs). The origin of

edge states can be understood by the consequences of finite Zak phase of bulk wave function of graphene. Zak phase is one-dimensional version of Berry phase (Zak, 1989).

In this chapter, we give an overview of topological aspects on electronic properties of graphene. We start with the basics of π -electronic states of graphene using tight-binding model, and derive the massless Dirac equation to show the singular topological properties at Fermi points. Further, we give the overview of edge effect on π -electronic states of graphene on the basis of GNRs, where it is shown that zigzag edges provide robust topological edge states. Finally, we give analytic properties of energy spectrum for GNRs and carbon nanotubes.

Electronic state of graphene

We employ a single-orbital nearest-neighbor tight-binding model for the π -electron network to describe the electronic states of graphene (Neto et al., 2009; Wallace, 1947). Fig. 1A and B show the lattice structure and the first Brillouin zone (BZ) of graphene, respectively. The corners of the first BZ are called K_+ or K_- points, which are also referred to as Dirac points because the energy spectrum at these corners can be described by the massless Dirac equation (Weyl equation).

Let us define the wave functions at R_A of a lattice site A and R_B of a lattice site B as $\psi_A(R_A)$ and $\psi_B(R_B)$, respectively. These wave functions can be related by the following Schrödinger equations of the tight-binding model;

$$E\psi_A(R_A) = -\gamma_0 \sum_{l=1}^3 \psi_B(R_A - \tau_l), \quad (1)$$

Fig. 1 (A) Graphene sheet in real space, where the black (white) circles denote A(B)-sublattice sites; a is the lattice constant and $\mathbf{a}_1 = (a, 0)$ and $\mathbf{a}_2 = (-a/2, \sqrt{3}a/2)$ are the primitive vectors. (B) First BZ of graphene. $\mathbf{K}_+ = \frac{2\pi}{a}(\frac{1}{3}, \frac{1}{\sqrt{3}})$, $\mathbf{K}_- = \frac{2\pi}{a}(\frac{2}{3}, 0)$, $\Gamma = (0, 0)$. Note that there are three $\mathbf{K}_+$ and $\mathbf{K}_-$ points, which can be connected by the reciprocal lattice vectors. The valence and conduction bands are in contact at the degeneracy points, $\mathbf{K}$ and $\mathbf{K}'$. (C) Energy band structure of graphene within the irreducible BZ, together with DOS of a graphene sheet. (D) (left) 3D plot of the energy band structure for π -electrons. (right) Zoom of energy band structure around $\mathbf{K}$ -points, where the energy dispersion has conical shape, i.e., Dirac cone.

$$E\psi_B(\mathbf{R}_B) = -\gamma_0 \sum_{l=1}^3 \psi_A(\mathbf{R}_B + \boldsymbol{\tau}_l). \quad (2)$$

Here E is the eigenenergy. $\mathbf{R}_A = n_1 \mathbf{a}_1 + n_2 \mathbf{a}_2 + \boldsymbol{\tau}_3$ and $\mathbf{R}_B = n_1 \mathbf{a}_1 + n_2 \mathbf{a}_2$, where integers n_1 and n_2 represent the locations of sites A and B, respectively. $\boldsymbol{\tau}_3 = (a/2, -a/2\sqrt{3})$ is the relative vector between A and B atoms. $a = 2.46 \text{ \AA}$ is the lattice constant of graphene. γ_0 is the transfer integral between nearest-neighbor carbon sites, which has been estimated to be about 2.75 eV in a graphene system.

Here we assume a plane wave form of the wave function, i.e., $\psi_A(\mathbf{R}_A) \propto f_A(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{R}_A)$ and $\psi_B(\mathbf{R}_B) \propto f_B(\mathbf{k}) \exp(i\mathbf{k} \cdot \mathbf{R}_B)$, where $\mathbf{k} = (k_x, k_y)$ is the wavenumber vector. Thus, we obtain the eigenvalue equation

$$H(\mathbf{k}) \begin{pmatrix} f_A(\mathbf{k}) \\ f_B(\mathbf{k}) \end{pmatrix} = E \begin{pmatrix} f_A(\mathbf{k}) \\ f_B(\mathbf{k}) \end{pmatrix}, \quad (3)$$

with the Hamiltonian

$$H(\mathbf{k}) = \begin{pmatrix} 0 & h^*(\mathbf{k}) \\ h(\mathbf{k}) & 0 \end{pmatrix}. \quad (4)$$

Here

$$h(\mathbf{k}) = -\gamma_0 (1 + e^{-ik a_1} + e^{-ik a_2}) = -\gamma_0 |h(\mathbf{k})| e^{i\phi_k}, \quad (5)$$

and ϕ_k is the phase measured from k_x axis. Thus, the energy bands are given by $E_s = s |f(\mathbf{k})|$, namely,

$$E_s(\mathbf{k}) = s\gamma_0 \sqrt{1 + 4 \cos \frac{k_x a}{2} \cos \frac{\sqrt{3} k_y a}{2} + 4 \cos^2 \frac{k_x a}{2}} \quad (6)$$

with $s = \pm 1$. Because one carbon site has one π -electron on average, only the $E_-(\mathbf{k})$ band is completely occupied. Thus, $s = +1$ and $s = -1$ correspond to the conduction and valence bands, respectively. The wave function can be written as

$$\begin{pmatrix} f_A(\mathbf{k}) \\ f_B(\mathbf{k}) \end{pmatrix} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ s e^{i\phi_k} \end{pmatrix}. \quad (7)$$

Thus, the Bloch wave function of graphene has a relative phase between A and B sublattice sites. The density of states (DOS) is calculated as

$$D(E) = -\frac{1}{\pi} \text{Im} \sum_{s=\pm} \int_{1\text{stBZ}} d\mathbf{k} \frac{1}{E - E_s(\mathbf{k}) + i\eta}, \quad (8)$$

where the $\mathbf{k}$ -integration is over the first BZ and η is an infinitesimally small real number.

Fig. 1C shows the energy band structure of graphene for π -electrons and corresponding DOS. Fig. 1D shows 3D plot of the energy band structure. Near the Γ point, both valence and conduction bands can be expressed as quadratic functions of k_x and k_y , i.e., $E(\mathbf{k}) = \pm \gamma_0 (3 - 3|\mathbf{k}|^2/4)$. At the M points, which are the midpoints of the sides of the hexagonal first BZ, a saddle point appears in the energy dispersion in the vicinity of $E = \pm \gamma_0$, resulting in logarithmic divergence of the DOS as can be seen in Fig. 1C. Near the K point at the corner of the hexagonal first BZ, the energy dispersion is a linear function of the magnitude of the wave vector, $E(\mathbf{k}) = \pm \sqrt{3} \gamma_0 a |\mathbf{k}|/2$, where the DOS linearly depends on energy. Here $a = (|\mathbf{a}_i| (i = 1, 2))$ is the lattice constant. The Fermi energy is located at the K points, and there is no energy gap at these points because $E(\mathbf{k})$ vanishes there owing to the hexagonal symmetry. Owing to the linear dispersion at K points, graphene has the conical dispersion as shown in the zoom of Fig. 1D. The slope of the conical dispersion gives the Fermi velocity v_F of graphene, i.e.,

$$v_F = \frac{1}{\hbar} \nabla_{\mathbf{k}} E(\mathbf{k}) = \frac{\sqrt{3}}{2} \frac{\gamma_0 a}{\hbar}, \quad (9)$$

which is approximately $v_F \sim 10^6$ m/s. Hence, the Fermi velocity of graphene is about 1/300 of the speed of light.

The electronic state in the vicinity of a K point can be described by the massless Dirac equation, i.e., Weyl equation (Ajiki and Ando, 1993; Ando et al., 1998). In the continuum limit of lattice coordination, the wave function around $\mathbf{K}_+$ point can be written as

$$\begin{cases} \psi_A(\mathbf{r}) = e^{i\mathbf{K}_+ \cdot \mathbf{r}} \phi_A^{\mathbf{K}_+}(\mathbf{r}) \\ \psi_B(\mathbf{r}) = e^{i\mathbf{K}_+ \cdot \mathbf{r}} \phi_B^{\mathbf{K}_+}(\mathbf{r}) \end{cases} \quad (10)$$

Here $\phi_A^{\mathbf{K}_+}(\mathbf{r})$ and $\phi_B^{\mathbf{K}_+}(\mathbf{r})$ are the envelope functions for A and B sublattice at the electron coordinate $\mathbf{r} = (x, y)$. Applying the Taylor expansion after we substitute these form into the tight-binding equations, we obtain the following equation,

$$\gamma \begin{pmatrix} 0 & \hat{k}_x - i\hat{k}_y \\ \hat{k}_x + i\hat{k}_y & 0 \end{pmatrix} \boldsymbol{\Phi}^{\mathbf{K}_+}(\mathbf{r}) = E \boldsymbol{\Phi}^{\mathbf{K}_+}(\mathbf{r}), \quad (11)$$

where $\boldsymbol{\Phi}^{\mathbf{K}_+}(\mathbf{r})$ is two-component envelope functions

$$\Phi^{K_+}(\mathbf{r}) = \begin{pmatrix} \phi_{A^+}^{K_+}(\mathbf{r}) \\ \phi_{B^+}^{K_+}(\mathbf{r}) \end{pmatrix}. \quad (12)$$

$\hat{k}_x$ and $\hat{k}_y$ are wave number operators and are replaced with the differential operators of the coordinates $\hat{k}_x \rightarrow -i\frac{\partial}{\partial x}$ and $\hat{k}_y \rightarrow -i\frac{\partial}{\partial y}$. The band parameter γ is given by

$$\gamma = \frac{\sqrt{3}a}{2}\gamma_0. \quad (13)$$

Similarly, for K_- point, we have

$$\gamma \begin{pmatrix} 0 & \hat{k}_x + i\hat{k}_y \\ \hat{k}_x - i\hat{k}_y & 0 \end{pmatrix} \Phi^{K_-}(\mathbf{r}) = E\Phi^{K_-}(\mathbf{r}). \quad (14)$$

Eq. (11) is mathematically equivalent to the two-dimensional version of Weyl equation, which describes the motion of massless relativistic particle, and also refereed as massless Dirac equation. The discussion can be also extended to multi-layer graphene and twisted bilayer graphene (Bistritzer and MacDonald, 2011; Guinea et al., 2006; Koshino and Ando, 2007; Koshino et al., 2018; McCann and Fal'ko, 2006; Nilsson et al., 2006).

In terms of the Pauli spin matrices

$$\sigma_x = \begin{pmatrix} 0 & 1 \\ 1 & 0 \end{pmatrix}, \sigma_y = \begin{pmatrix} 0 & -i \\ i & 0 \end{pmatrix}, \sigma_z = \begin{pmatrix} 1 & 0 \\ 0 & -1 \end{pmatrix}, \quad (15)$$

Eq. (11) can be written as

$$\gamma \boldsymbol{\sigma} \cdot \hat{\mathbf{k}} \Phi^{K_+}(\mathbf{r}) = E\Phi^{K_+}(\mathbf{r}), \quad (16)$$

where $\boldsymbol{\sigma} = (\sigma_x, \sigma_y)$ and $\hat{\mathbf{k}} = (\hat{k}_x, \hat{k}_y)$. Similarly, Eq. (14) can be rewritten as

$$\gamma \boldsymbol{\sigma}^* \cdot \hat{\mathbf{k}} \Phi^{K_-}(\mathbf{r}) = E\Phi^{K_-}(\mathbf{r}), \quad (17)$$

where $\boldsymbol{\sigma}^* = (\sigma_x, -\sigma_y)$.

The energy spectrum and eigenfunction of massless Dirac equation can be obtained by assuming the plane wave form as a solution of the envelope function, namely,

$$\Phi^{K_{\pm}}(\mathbf{r}) \propto \begin{pmatrix} f_A \\ f_B \end{pmatrix} \exp(i\mathbf{k} \cdot \mathbf{r}). \quad (18)$$

Here it should be noted that the wave number $\mathbf{k}$ is measured from either K_+ or K_- point. From this, we can immediately obtain the linear spectrum of energy as

$$E_S(\mathbf{k}) = s\gamma|\mathbf{k}|, \text{ with } s = \pm 1. \quad (19)$$

The wave function can be written as

$$\Phi_{sk}^K(\mathbf{r}) = \frac{1}{\sqrt{L_x L_y}} \exp(i\mathbf{k} \cdot \mathbf{r}) \Phi_{sk}^K, \quad (20)$$

with the *spin* sector

$$\Phi_{sk}^{K_{\pm}} = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ s e^{\mp i\theta_k} \end{pmatrix}. \quad (21)$$

Here θ_k is defined as the angle between wave vector $\mathbf{k}$ and the k_x -axis, i.e., $k_x + ik_y = |\mathbf{k}| e^{i\theta_k}$. Note that the term “spin” appearing here does not mean the real spin of the electron, since the eigenfunction for the *spin sector* describes the amplitude of the wave function on A and B sublattices. Thus, it is normally called *pseudo-spin* to distinguish it from the real electron spin. It should be noted that K_+ and K_- points have opposite phase θ_k . Using Eq. (19), Eq. (16) can be rewritten as

$$\frac{\boldsymbol{\sigma} \cdot \hat{\mathbf{k}}}{|\mathbf{k}|} \Phi^{K_+}(\mathbf{r}) = s\Phi^{K_+}(\mathbf{r}). \quad (22)$$

It should be noted that $\frac{\boldsymbol{\sigma} \cdot \hat{\mathbf{k}}}{|\mathbf{k}|}$ represents the helicity operator. Thus, the helicity of electrons in graphene depends on the band index s . Similarly, the expectation value of pseudo-spin around K_+ point is given as

$$\langle \boldsymbol{\sigma} \rangle = (\langle \sigma_x \rangle, \langle \sigma_y \rangle) = s(\cos \theta_k, \sin \theta_k). \quad (23)$$

These results indicate that the electron (hole) near K_+ point has a definite pseudo-spin direction, which is parallel (antiparallel) to the direction of motion. These properties are also refereed as *chirality*. For the state near K_- point, the chirality is obtained by reversing the sign of s , i.e., $s \rightarrow -s$. Thus, K_+ and K_- have opposite chirality from each other, which is the consequences of

two-dimensional analog of the Fermion doubling (Aoki and Dresselhaus, 2014). In addition, the chiral property of wave function leads to the Klein tunneling effect (Katsnelson, 2012; Katsnelson et al., 2006).

Topological properties of graphene

The wave function of pseudo-spin sector contains the nontrivial Berry phase (Ando et al., 1998). To see this fact further, here we briefly summarize the key results for topological aspects (Bernevig and Hughes, 2013; Berry, 1984; Vanderbilt, 2018; Xiao et al., 2010). Now let us consider a physical system in which Hamiltonian H smoothly depends on the parameter $\mathbf{R}$, i.e., $H = H(\mathbf{R})$. This parameter slowly changes with time and moves along an arbitrary enclosed path C in $\mathbf{R}$ space. To be more specific, let us denote $t = 0$ as the initial time, and $t = T$ as the final time, so the $\mathbf{R}(t)$ satisfies $\mathbf{R}(0) = \mathbf{R}(T)$ for a closed path. Now we consider the time-evolution of wave function. The time-dependent Schrödinger equation is

$$H(\mathbf{R}(t))|\psi(t)\rangle = i\hbar \frac{\partial}{\partial t} |\psi(t)\rangle. \quad (24)$$

For each time, we assume that the wave function satisfies the orthonormal basis set $\{|\phi_n(\mathbf{R}(t))\rangle\}$ with the eigenvalue equation

$$H(\mathbf{R}(t))|\phi_n(t)\rangle = E_n(\mathbf{R}(t))|\phi_n(t)\rangle. \quad (25)$$

By assuming that the wave function adiabatically changes, the wave function at time t can be written as

$$|\phi_n(t)\rangle = e^{i\gamma_n(t)} |\phi_n(\mathbf{R}(t))\rangle. \quad (26)$$

In general, the phase $\gamma_n(t)$ does not need to be zero. Substituting $|\phi_n(t)\rangle$ into Eq. (24), we obtain

$$E_n(\mathbf{R}_n)|\phi_n(\mathbf{R})\rangle = \hbar \left(\frac{d}{dt} \gamma_n \right) |\phi_n(\mathbf{R})\rangle + i\hbar \frac{d}{dt} |\phi_n(\mathbf{R})\rangle.$$

Taking the inner product with $\langle \phi_n(\mathbf{R})|$, we obtain

$$\begin{aligned} i \frac{\partial}{\partial t} \gamma_n &= -\frac{i}{\hbar} E_n(\mathbf{R}) - \langle \phi_n(\mathbf{R}) | \frac{\partial}{\partial t} | \phi_n(\mathbf{R}) \rangle \\ &= -\frac{i}{\hbar} E_n(\mathbf{R}) - \langle \phi_n(\mathbf{R}) | \nabla_{\mathbf{R}} | \phi_n(\mathbf{R}) \rangle \cdot \frac{\partial \mathbf{R}}{\partial t}. \end{aligned}$$

Since we are considering a closed path for the parameter $\mathbf{R}$, the system Hamiltonian returns to the initial state after the time T . However, the phase difference between the initial and last time is as follows.

$$\begin{aligned} &\gamma_n(T) - \gamma_n(0) \\ &= \int_0^T \frac{\partial \gamma_n(t)}{\partial t} dt \\ &= -\frac{1}{\hbar} \int_0^T E_n(\mathbf{R}(t)) dt + i \oint_C \langle \phi(\mathbf{R}) | \nabla_{\mathbf{R}} | \phi(\mathbf{R}) \rangle \cdot d\mathbf{R} \end{aligned} \quad (27)$$

The first term is the conventional dynamical phase. The second part is the geometric phase which depends on the path C , and called Berry phase. When we define the Berry connection $A_n(\mathbf{R})$ as

$$A_n(\mathbf{R}) = -i \langle \phi(\mathbf{R}) | \nabla_{\mathbf{R}} | \phi(\mathbf{R}) \rangle, \quad (28)$$

we can rewrite the Berry phase as

$$\gamma_n[C] = -\oint_C A_n(\mathbf{R}) \cdot d\mathbf{R}. \quad (29)$$

Physically, the Berry connection can be understood as the vector potential in $\mathbf{R}$ space, and its rotation $\mathbf{F}(\mathbf{R}) = \nabla \times \mathbf{A}(\mathbf{R})$ can be understood as the magnetic field in $\mathbf{R}$ space, which is called Berry curvature. Using Stokes' theorem, the line integral can be written as surface integral

$$\gamma_n[C] = -\oint_S \nabla \times \mathbf{A}_n(\mathbf{R}) \cdot d\mathbf{S} = -\oint_S \mathbf{F}_n(\mathbf{R}) d\mathbf{S} \quad (30)$$

Thus, the Berry phase can be understood as arising from magnetic flux in $\mathbf{R}$ space.

Let us now consider the electronic states of graphene near $K_{\pm}$ points, i.e., Dirac cone. We consider the Bloch wave vector $\mathbf{k}$ as the parameter of Hamiltonian $H(\mathbf{k})$. From Eq. (21), we can immediately calculate the Berry connection as follows,

$$A_s^{K_{\pm}}(\mathbf{k}) = \langle \Phi_{sk}^{K_{\pm}} | \nabla_{\mathbf{k}} | \Phi_{sk}^{K_{\pm}} \rangle = \mp \frac{1}{2} \nabla_{\mathbf{k}} \theta_{\mathbf{k}}. \quad (31)$$

It should be noted that K_+ and K_- points have opposite signs for Berry connection. The Berry phase is obtained by the line integration along a closed path with anti-clockwise direction, i.e.,

$$\begin{aligned}\gamma_s^{K_{\pm}}[C] &= \oint_C A_s^{K_{\pm}}(\mathbf{k}) \cdot d\mathbf{k} \\ &= \begin{cases} \mp\pi & \text{if } C \text{ encloses } \mathbf{k} = \mathbf{0}, \\ 0 & \text{if } C \text{ does not enclose } \mathbf{k} = \mathbf{0}. \end{cases}\end{aligned}\quad (32)$$

If we recall that the Berry connection $A(\mathbf{k})$ is the vector potential in $\mathbf{k}$ space, the Berry phase indicates the magnetic flux through the area enclosed by the path C . Thus, there is a magnetic flux at $\mathbf{k} = \mathbf{0}$ with the magnitude of π , i.e.,

$$F_s^{K_{\pm}}(\mathbf{k}) = \pm\pi\delta(\mathbf{k}). \quad (33)$$

We should note that the Berry curvature only exists at Dirac point.

In general, if the system has time-reversal symmetry, Berry curvature satisfies $F(\mathbf{k}) = -F(-\mathbf{k})$. If the system has the crystal inversion symmetry, Berry curvature satisfies $F(\mathbf{k}) = F(-\mathbf{k})$. Hence, if the system has both time-reversal and crystal inversion symmetries, Berry curvature becomes $F(\mathbf{k}) = 0$. Since K_+ and K_- points are connected with the time-reversal symmetry, they have opposite Berry curvature. However, as can be seen below, at Dirac K_+ and K_- points, graphene acquires non-zero Berry curvature but opposite sign. Owing to this topological singularity, the Boltzmann conductivity of graphene at $E = 0$ gives the universal value $e^2/\pi h$ even in the vanishing of density of states (Ando, 2005).

In later section, we will inspect Zak phase (also known as $\mathcal{Z}_2$ Berry phase or one-dimensional version of Berry phase) of graphene. Zak phase illustrates the topological origin of graphene edge states.

Graphene nanoribbons and edge states

The presence of a graphene edge has a strong impact on the electronic states of Dirac electrons. In this section, we briefly summarize the electronic structures of GNRs using the tight-binding model to see the edge effect on the electronic states of graphene.

There are two types of graphene edges: *armchair* and *zigzag* edges. These two edges have a 30° difference in their orientation within the graphene sheet. A large difference in the π -electronic structures is induced by the two types of graphene edges (Fujita et al., 1996). In particular, a zigzag edge exhibits localized states, whereas an armchair edge does not exhibit such localized states. The origin of edge state is the topological properties of bulk wave function, which will be explained in the next section.

The lattice structures of GNRs are shown in Fig. 2A and B. Fig. 2A shows a schematic of AGNR. The primitive vector for AGNR is $\mathbf{a} = (0, a_T)$, where $a_T = \sqrt{3}a$ with a being the lattice constant of graphene. Fig. 2B shows a schematic of ZGNR. Similarly, the primitive vector for this system is given by $\mathbf{a} = (a, 0)$. We define the width of GNRs as N , where N is the number of dimer (two carbon sites) lines for AGNRs and the number of zigzag lines for ZGNRs.

It is assumed that all dangling bonds at graphene edges are terminated by hydrogen atoms and thus do not contribute to the electronic states near the Fermi level. We employ a single-orbital tight-binding model for the π -electron network. Details of the calculation of the eigenenergy spectrum and eigenfunctions are described in the last section. Here we briefly overview the electronic

Fig. 2 Structure of graphene nanoribbons with (A) armchair edges (armchair ribbon) and (B) zigzag edges (zigzag ribbon). The dashed rectangles define the unit cells; a_T and a are the respective unit cell widths for armchair and zigzag nanoribbons; N defines the ribbon width. The $\times$ marks indicate the missing carbon atoms for the edge boundary condition. The nanoribbon width is defined as $W = \frac{1}{2}(N+1)a$ for armchair nanoribbons and $W = \frac{\sqrt{3}}{2}Na + \frac{a}{\sqrt{3}}$ for zigzag nanoribbons.

states of GNRs. Experimentally, GNRs can be fabricated by using either bottom-up (Cai et al., 2010) or top-down technology (Baringhaus et al., 2014; Han et al., 2007; Kosynkin et al., 2009).

Fig. 3A–C show the DOS and energy band structures of AGNRs for three different ribbon widths. The top of the valence band and the bottom of the conduction band are located at $ka = 0$. Note that the ribbon width determines whether the system is metallic or semiconducting. As shown in Fig. 3B, the system is metallic when $N = 3m - 1$, where $m = 1, 2, 3, \dots$. For semiconducting ribbons, the direct band gap decreases with increasing ribbon width and approaches zero in the limit of very large N . For narrow undoped metallic AGNR, an energy gap can be formed by Peierls instabilities at low temperatures (Fujita et al., 1996), which is consistent with density functional theory (DFT) calculations (Son et al., 2006a).

For ZGNRs, however, a remarkable feature arises in the band structure, as shown in Fig. 4A–C. The top of the valence band and the bottom of the conduction band are always degenerate at $k = \pi/a$, and the degeneracy of the center bands at $k = \pi/a$ does not originate from the intrinsic band structure of graphene. These two special center bands flatten with increasing ribbon width. A pair of partial flat bands appears within the region $2\pi/3a \leq |k| \leq \pi/a$, where the bands are located in the vicinity of the Fermi level.

The electronic states in the partial flat bands of ZGNRs can be understood as localized states near the zigzag edge by examining the charge density distribution (Fujita et al., 1996; Nakada et al., 1996; Wakabayashi et al., 1999). The emergence of the edge states can be explained by considering a semi-infinite graphene sheet with a zigzag edge. First, we show the distribution of charge density in flat band states for different wave numbers in Fig. 5A–D, where the amplitude is proportional to the circle radius. The wave function has a non-bonding character, i.e., it only has a finite amplitude on one of the two sublattices that include the edge sites. It is completely localized at the edge site when $ka = \pi$ and starts to gradually penetrate into the inner sites when ka deviates from π , reaching an extended state at $k = 2\pi/3a$.

Considering the translational symmetry, we can start constructing the analytical solution for the edge state by letting the Bloch components of the linear combination of atomic orbitals (LCAO) wave function be $\dots, e^{ika(n-1)}, e^{ikan}, e^{ika(n+1)}, \dots$ on successive edge sites, where n denotes a site located on the edge. Then, the mathematical condition necessary for the wave function to be exact for $E = 0$ is that the sum of the components of the complex wave function over the nearest neighbor sites becomes zero. In Fig. 5E, the above condition implies that $e^{ika(n+1)} + e^{ikan} + x = 0$, $e^{ikan} + e^{ika(n-1)} + y = 0$ and $x + y + z = 0$. Therefore, the wave function components x , y and z are found to be $D_k e^{ika(n+1/2)}$, $D_k e^{ika(n-1/2)}$ and $D_k^2 e^{ikan}$, respectively. Here, $D_k = -2 \cos(ka/2)$. Thus, the charge density is proportional to $D_k^{2(m-1)}$ at each non-nodal site of the m -th zigzag chain from the edge. Then the convergence condition $|D_k| \leq 1$ is required, for otherwise the wave function would diverge in a semi-infinite graphene sheet. This convergence condition defines the region $2\pi/3a \leq |k| \leq \pi/a$, where the flat bands appear.

Fig. 3 Energy band structure $E(k)$ and DOS $D(E)$ of armchair ribbons of various widths: (A) $N = 4$, (B) $N = 5$ and (C) $N = 30$.

Fig. 4 Energy band structure $E(k)$ and DOS $D(E)$ of zigzag ribbons of various widths: (A) $N = 4$, (B) $N = 5$ and (C) $N = 30$.

Fig. 5 Charge density plot for analytical solution of the edge states in a semi-infinite graphene sheet for several wave numbers: (A) $k = \pi/a$, (B) $k = 8\pi/9a$, (C) $k = 7\pi/9a$ and (D) $k = 2\pi/3a$. (E) Analytical form of the edge state for a semi-infinite graphene sheet with a zigzag edge, shown by the bold lines. Each carbon site is specified by a location index n on the zigzag chain and by a chain order index m , which increases from the edge. The magnitude of the charge density at each site, such as x , y and z , is obtained analytically (see text). The radius of each circle is proportional to the charge density on each site, and the drawing corresponds to $k = 7\pi/9a$.

The graphene edge states give rise to large contribution to DOS at the Fermi energy when the system size has a nanometer scale. Even a weak electron-electron interaction gives the spin polarized states with ferrimagnetic correlation along the zigzag edge (Fujita et al., 1996; Son et al., 2006a). Such magnetic states involve particular interests for the application of spintronics devices (Son et al., 2006b).

Charge polarization and Zak phase

Charge polarization can be expressed in terms of geometric center of electronic wave functions (King-Smith and Vanderbilt, 1993; Marzari et al., 2012; Resta, 1994; Vanderbilt and King-Smith, 1993; Zak, 1989). For one-dimensional (1D) crystalline system, the charge polarization of n -th energy band is given as a Wannier center, i.e., $P_n = \langle w_n(x) | x | w_n(x) \rangle$, where $w_n(x)$ is a Wannier function of n -th energy band (Marzari et al., 2012). Owing to gauge freedom of Wannier functions, P_n is well-defined up to a lattice constant. The edge states of zigzag edge can be understood as a charge polarization owing to the nontrivial topological phase of bulk wave function (Delplace et al., 2011; Hatsugai, 2009; Ryu and Hatsugai, 2002). In this section, we relate the appearance of edge states at graphene zigzag edges to the finite Zak phase of bulk wave function of graphene.

To relate P_n to Berry connection, one can apply Fourier transformation to w_n and x , which results in (Marzari et al., 2012)

$$P_n = \frac{1}{2\pi} \int_0^{2\pi} \langle \psi_n | i\partial k | \psi_n \rangle dk, \quad (34)$$

where ψ_n is the periodic part of Bloch function of n -th energy band, and $A_n = \langle \psi_n | i\partial k | \psi_n \rangle$ is Berry connection. We refer to the integration part of Eq. (34) as Zak phase (Zak, 1989).

In a finite chain, fractional charges $P = \pm \sum_n^{\text{occ}} P_n$ accumulate at the ends of the chain, where the summation is taken over all the occupied energy bands. When inversion symmetry is present, P_n is quantized to 0 or 1/2. In following discussions, we interchangeably use *Zak phase* and *charge polarization* to mean the same quantity.

In 2D crystalline system, Eq. (34) has the dependence of wavenumber. Charge polarization is given as

$$P_n(k) = \frac{1}{|\mathcal{D}|} \oint_{\mathcal{D}} A_n(k, k_{\perp}) dk_{\perp}, \quad (35)$$

where $A_n(k, k_{\perp}) = \langle \psi_n(\mathbf{k}) | i\partial_{k_{\perp}} | \psi_n(\mathbf{k}) \rangle$ is Berry connection of n -th energy band in 2D momentum space. Here, k is the wavenumber along longitudinal translational invariant direction of GNR. $k_{\perp}$ is perpendicular to k , i.e., transverse direction of GNRs. $\mathcal{D}$ is a straight path connecting two equivalent $\mathbf{k}$ points in momentum space along $k_{\perp}$ direction. Similar to 1D systems, fractional charge $\sum_n^{\text{occ}} P_n \cdot \mathbf{n}_i$ accumulates on the edge if a material possesses finite charge polarization.

To calculate Zak phase, we use the periodic part of bulk wave function given as Eq. (7), i.e.,

$$|\psi_{\mathbf{k}}\rangle = \frac{1}{\sqrt{2}} \begin{pmatrix} 1 \\ se^{i\phi_{\mathbf{k}}} \end{pmatrix}. \quad (36)$$

Thus, the Berry connection along $k_{\perp}$ for the valence band is

$$A(k, k_{\perp}) = -\frac{1}{2} \partial_{k_{\perp}} \phi_{\mathbf{k}}. \quad (37)$$

The Zak phase is

$$\mathcal{Z}(k) = \oint_{\mathcal{P}} \mathbf{A}(k, k_{\perp}) dk_{\perp} = -\frac{1}{2} \oint_{\mathcal{P}} \partial_{k_{\perp}} \phi_k. \quad (38)$$

Thus, the Zak phase is given as the integration of phase ϕ_k along the path $\mathcal{P}$. Zak phase becomes zero if the integration path is taken in a simply connected region, otherwise Zak phase becomes finite. Fig. 6A shows reciprocal space of graphene and the integration path for Zak phase calculation. $\mathcal{P}_A(k)$ and $\mathcal{P}_Z(k)$ are the integration path for AGNR and ZGNR, respectively. Since the zigzag edge is parallel to a_1 , k is parallel to k_x . Thus, the integration path $\mathcal{P}_Z(k)$ should be taken along k_y for ZGNR. Similarly, armchair edges are parallel to y , i.e., $(-a_1 + a_2)/2$, k is parallel to $\mathbf{b}_1 - \mathbf{b}_2$. Hence, the integration path $\mathcal{P}_A(k)$ should be taken along $\mathbf{b}_1 + \mathbf{b}_2$ for AGNR.

Fig. 6B shows the phase mapping of ϕ_k in the momentum space. The phase jumps of 2π periodically appear along the direction of $\mathbf{b}_1 + \mathbf{b}_2$. Hence, the integration path $\mathcal{P}_Z(k)$ crosses the phase jump if $2\pi/3a < |k| < \pi/a$, resulting in finite Zak phase. However, no such phase jump appear for the path $\mathcal{P}_A(k)$ for arbitrary k .

For AGNR, the Zak phase is identically zero, i.e.

$$\mathcal{Z}(k) = 0. \quad (39)$$

However, for ZGNR, the Zak phase is

$$\mathcal{Z}(k) = \begin{cases} \pi, & 2\pi/3a < |k| < \pi/a, \\ 0, & |k| < 2\pi/3a. \end{cases} \quad (40)$$

The k -region of finite Zak phase coincides with the region of zigzag edge states. Hence, the edge states are attributed to the Zak phase of bulk wave function. The finite Zak phase tells us the existence of edge states. This discussion can be applied to bearded edges (Delplace et al., 2011) and corner states of graphene (Liu and Wakabayashi, 2021). The reason why the edge states appear at $E = 0$ is supported by the particle-hole (chiral) symmetry of graphene (Ryu and Hatsugai, 2002).

Energy spectrum and wave functions: Graphene nanoribbons

In this section, we briefly summarize the analytic solutions of energy spectrum and wave functions for GNRs on the basis of tight-binding model (Wakabayashi et al., 2010).

Armchair nanoribbons

The set of equations of motion for AGNRs based on the nearest-neighbor tight-binding model is described by

Fig. 6 (A) Reciprocal space of graphene sheet. $\mathbf{b}_1 = \frac{2\pi}{a}(1, 1/\sqrt{3})$, $\mathbf{b}_2 = \frac{2\pi}{a}(0, 2/\sqrt{3})$ are primitive reciprocal vectors. The magenta (cyan) rectangle zone represents the translational invariance of armchair (zigzag) edges. $\mathcal{P}_A(k)$ and $\mathcal{P}_Z(k)$ are the integration path for calculation of Zak phase of armchair and zigzag edges, respectively. (B) Phase mapping of ϕ_k which is the phase of bulk wave function. The phase jumps of 2π periodically appears along the direction of $\mathbf{b}_1 + \mathbf{b}_2$. When the integration path for Zak phase crosses the phase jump line, finite Zak phase is obtained. (C) Energy band structure and corresponding Zak phase $\mathcal{Z}(k)$ for (top panel) ZGNR and (bottom) AGNR. ZGNR has finite Zak phase π for $2\pi/3 < |k| \leq \pi$ (indicated by yellow rectangles).

$$(E/\gamma_0)\psi_{m,A} = -e^{-ik/2}\psi_{m,B} - \psi_{m-1,B} - \psi_{m+1,B}, \quad (41)$$

$$(E/\gamma_0)\psi_{m,B} = -e^{+ik/2}\psi_{m,A} - \psi_{m-1,A} - \psi_{m+1,A}, \quad (42)$$

where $m = 1, 2, 3, \dots, N$. $\psi_{m,A}$ and $\psi_{m,B}$ are the wave functions at the mA and mB -sites, respectively. The site indices are given in Fig. 2A. The boundary condition for AGNRs is

$$\psi_{0,A} = \psi_{0,B} = \psi_{N+1,A} = \psi_{N+1,B} = 0. \quad (43)$$

The energy spectrum for AGNRs is given as

$$E_s = s\gamma_0 \sqrt{1 + 2\varepsilon_p \cos\left(\frac{k}{2}\right) + \varepsilon_p^2}, \quad (44)$$

where p is the wave number in the transverse direction. Here, $\varepsilon_p = 2 \cos(p)$ and $s = \pm 1$; $s = +1$ ($s = -1$) corresponds to the conduction (valence) energy band. Note that E_s becomes zero at $k = 0$ and $p = 2\pi/3$, which corresponds to a Dirac point. The transverse wave number p is quantized owing to the ribbon boundary condition as

$$p = \frac{r}{N+1}\pi, \quad r = 1, 2, 3, \dots, N. \quad (45)$$

Note that $E_s = 0$ at $k = 0$ whenever $N = 3m - 1$ ($m = 1, 2, 3, \dots$), which is simply the condition for metallic AGNRs.

Fig. 7A shows the relation between the BZ of graphene and that of AGNRs. The hexagonal BZ of graphene is mapped onto the bold black line on the k_y -axis ($-\pi \leq k_y \leq \pi$) as the BZ of AGNRs. The shaded rectangle corresponds to the phase space of variables k and p of Eq. (44). Note the range of p is $0 \leq p \leq \pi$. The five red lines parallel to the k_y -axis correspond to the cutting lines of the case for AGNR of $N = 5$ (metallic). The cutting line of $r = 4$ clearly passes through the Dirac point, i.e., the nanoribbon is metallic. Fig. 7B shows the energy band structure of AGNR ($N = 5$) with subband indices. In this case, since the cutting line of $r = 4$ gives $p = 2\pi/3$, the corresponding subband passes through the Dirac point, i.e., the nanoribbon has a metallic band structure with linear dispersion. Thus, the energy band structures of AGNRs can be obtained by slicing the band structure of graphene, as in the case of carbon nanotubes (Saito et al., 1991).

The wave function is written as

$$\begin{pmatrix} \psi_{m,A} \\ \psi_{m,B} \end{pmatrix} = N_c \begin{pmatrix} -s \\ \sqrt{\varepsilon_p + e^{+ik/2}} \\ \sqrt{\varepsilon_p + e^{-ik/2}} \end{pmatrix} \sin(mp). \quad (46)$$

Here N_c is the normalization constant.

Zigzag nanoribbons

The set of equations of motion for ZGNRs is given by

$$(E/\gamma_0)\psi_{m,A} = -\psi_{m-1,B} - g_k\psi_{m,B}, \quad (47)$$

Fig. 7 (A) Relation between the BZ of graphene and that of AGNRs. The hexagonal BZ of graphene is mapped onto the bold black line on the k_y -axis ($-\pi \leq k_y \leq \pi$) as the BZ of AGNRs. The shaded rectangle corresponds to the phase space of variables k and p of Eq. (44). Note the range of p is $0 \leq p \leq \pi$. The K and K' points of graphene BZ are mapped on to the red and blue circles on k_x -axis in the reduced BZ, respectively. The five red lines parallel to the k_y -axis correspond to the cutting lines of the case for the AGNR of $N = 5$ (metallic). The cutting line of $r = 4$ clearly passes through the Dirac point, i.e., the nanoribbon is metallic. (B) Energy band structure of AGNR ($N = 5$) with subband indices. The shaded area indicates the energy spectrum of bulk graphene.

$$(E/\gamma_0)\psi_{m,B} = -\psi_{m+1,A} - g_k\psi_{m,A}. \quad (48)$$

Here $g_k = 2 \cos(k/2)$ is originated from the Bloch phase, and the site index is $m = 0, 1, 2, \dots, N+1$. $\psi_{m,A}$ and $\psi_{m,B}$ describe the wave functions at the mA - and mB -sites, respectively. The site indices are given in Fig. 2B. The boundary condition for ZGNRs is given by $\psi_{0,B} = \psi_{N+1,A} = 0$.

The energy spectrum of ZGNRs is given as

$$E_s = s\gamma_0 \sqrt{1 + g_k^2 + 2g_k \cos(p)}, \quad (49)$$

where $s = \pm 1$, and $s = +1$ ($s = -1$) corresponds to the conduction (valence) energy band. The transverse wave number p is related with longitudinal wave number k as

$$F(p, N) \equiv \sin[pN] + g_k \sin[p(N+1)] = 0. \quad (50)$$

Fig. 8A shows the relation between the BZ of graphene and that of ZGNRs. The shaded rectangle corresponds to the phase space of variables k and p , i.e., $|k| < \pi$ and $0 \leq p \leq \pi$. The numerically obtained solutions of Eq. (50) are shown in Fig. 8B for the case of ZGNR with $N = 5$. Let us call the solutions $F(p, N) = 0$ for fixed N as p_r ($r = 1, 2, \dots, p_n$) within $0 < p < \pi$, i.e., excluding $p = 0$ and π . All these p_i solutions give the extended states. The number of p_r , i.e., p_n , depends on the region of k ,

$$p_n = \begin{cases} N, & |k| \leq k_c, \\ N-1, & k_c < |k| \leq \pi, \end{cases} \quad (51)$$

where k_c is given as

$$k_c = 2 \arccos\left(\frac{1}{2} \cdot \frac{1}{1 + 1/N}\right) \sim \frac{2}{3}\pi + \frac{2}{\sqrt{3}} \cdot \frac{1}{N}. \quad (52)$$

In the limit of large N , k_c converges to $2\pi/3$ which corresponds to the Dirac K point. In other words, the cutting lines never go through the Dirac points in ZGNRs.

One missing solution of Eq. (50) for the range of $k_c < |k| \leq \pi$ can be obtained by analytic continuation as

$$p \rightarrow \pi + i\eta. \quad (53)$$

Then, Eq. (50) is rewritten as

$$\sinh(\eta N) - g_k \sinh(\eta(N+1)) = 0, \quad (54)$$

which gives two solutions of η as shown in the Fig. 8B. The energy spectrum can be obtained by using

$$E_s = s\gamma_0 \sqrt{1 + g_k^2 - 2g_k \cosh \eta}, \quad (55)$$

which give the central partial flat bands in the region of $k_c < |k| \leq \pi$.

The wave function for extended states is written as

Fig. 8 (A) Relation between the BZ of graphene and that of ZGNRs. The shaded rectangle corresponds to the phase space of variables k and p of Eq. (50). The K and K' points of graphene BZ are mapped on to the red and blue circles on k -axis in the reduced BZ, respectively. (B) The cutting lines of the case for ZGNR of $N = 5$ in the k - p space. The cutting line of $r = 5$ has the imaginary component η for $|k| \geq |k_c|$, which corresponds to the mode of the partial flat bands due to the extended states. (C) Energy band structure of ZGNR ($N = 5$) with subband indices. The shaded area indicates the energy spectrum of bulk graphene.

$$\begin{pmatrix} \psi_{m,A} \\ \psi_{m,B} \end{pmatrix} = N_c \begin{pmatrix} (-1)^r s \sin(p(N+1-m)) \\ \sin(pm) \end{pmatrix} \quad (56)$$

with the normalization constant N_c . Thus, the wave function for the subband with odd (even) r has the even (odd) parity. Similarly the wave function for the edge states can be written as

$$\begin{pmatrix} \psi_{m,A} \\ \psi_{m,B} \end{pmatrix} = N'_c e^{i\pi m} \begin{pmatrix} (-1)^r s \sinh(\eta(N+1-m)) \\ \sinh(\eta m) \end{pmatrix}, \quad (57)$$

with a normalization constant N'_c .

Note that the wave function for AGNRs given by Eq. (46) has a phase difference between sublattice sites A and B due to the chiral nature of graphene. On the other hand, the wave function for ZGNRs is always real and thus has no phase, irrespective of whether the state is extended or localized. This difference in wave functions between AGNRs and ZGNRs is related to the nature of pseudospin in graphene. Although ZGNRs conserve the total time-reversal symmetry, pseudo-time-reversal symmetry (time-reversal symmetry in each valley) is broken owing to the edge states. This nature gives rise to the perfectly conducting channel of ZGNRs (Wakabayashi et al., 2007). It is also possible to derive the analytic wave function of GNRs from the massless Dirac equation (Brey and Fertig, 2006; Wakabayashi, 2000).

Electronic states of carbon nanotubes

The electronic states of GNRs are obtained by imposing the open boundary condition in one direction for the electronic states of graphene, and are characterized by the edge structures. In this section, we shall consider imposing the periodic boundary condition in one direction of graphene, which derives the electronic states of carbon nanotubes (CNTs).

CNT is a one-dimensional carbon nanomaterial which can be constructed by rolling a graphene into a cylinder form. It was discovered by S. Iijima in 1991 (Iijima, 1991). The structure of CNT is uniquely determined by the chiral vector C_h , which is defined as

$$C_h = na_1 + ma_2 \equiv (n, m). \quad (58)$$

Here m, n are integers and $0 \leq m \leq n$. In order to conform to commonly used notation in the research field of CNT, we have redefined the primitive vectors of graphene as $a_1 = \left(\frac{\sqrt{3}}{2}a, \frac{a}{2}\right)$, $a_2 = \left(\frac{\sqrt{3}}{2}a, -\frac{a}{2}\right)$, as shown in Fig. 9A. It should be noted that lattice structure is also rotated by 90 degree compared with Fig. 1A. The shortened notation (n, m) is widely used to characterize the geometry of CNT. In general, CNTs are classified as chiral ($0 < m < n$) and achiral ($m = 0$ or $m = n \neq 0$). Especially, $m = 0$ CNTs are known as zigzag nanotube, and $m = n$ CNTs are known as armchair nanotubes.

Fig. 9B shows the atomic structures of CNTs with several different chiral indices. Figs. 9C–F show the energy band structures and corresponding DOS for several different CNTs based on the nearest-neighbor tight-binding model. In general, CNTs are known to be metallic with linear dispersion when $m - n$ is multiple of 3, otherwise semiconducting with energy band gap (Hamada et al., 1992; Mintmire et al., 1992; Saito et al., 1991). Please also see the reviews for further details (Charlier et al., 2007; Laird et al., 2015; Saito et al., 1998). In the rest of this section, we shall explain the relation between the energy spectrum of CNTs and the energy band structure of graphene.

The structure of CNT can be characterized by its diameter d_t and chiral angle θ_t from a zigzag axis. Since the length of CNT circumference is $|C_h|$, the diameter d_t of CNT is given by

$$d_t = a\sqrt{n^2 + nm + m^2}/\pi. \quad (59)$$

The unit cell of a CNT is a rectangle bounded by the vector C_h and translational vector T as shown in the rectangle of Fig. 9A. The translational vector is given as

$$T = t_1 a_1 + t_2 a_2. \quad (60)$$

t_1 and t_2 are integers, which are determined by $C_h \cdot T = 0$ and $\text{gcm}(t_1, t_2) = 1$. Here, $\text{gcm}(m, n)$ means the great common measure of the two integers m and n . The area of CNT unit cell is calculated as $|C_h \times T| = \sqrt{3}a^2(n^2 + nm + m^2)/d_R$, where $d_R = \text{gcm}(2n + m, 2m + n)$. Using d_R , t_1 and t_2 can be written as $t_1 = (2m + n)/d_R$, $t_2 = -(2n + m)/d_R$. Dividing $|C_h \times T|$ by the area of the unit cell of graphene $|a_1 \times a_2| = \sqrt{3}a^2/2$, the number N of hexagons in unit cell of CNT can be obtained, i.e., $N = 2(n^2 + nm + m^2)/d_R$.

The unit vectors in the reciprocal lattice of graphene can be given as $b_1 = \frac{2\pi}{a}(1/\sqrt{3}, 1)$, $b_2 = \frac{2\pi}{a}(1/\sqrt{3}, -1)$. These vectors are derived by the relation $a_i \cdot b_j = 2\pi\delta_{ij}$, where δ_{ij} is the Kronecker delta. In similar manner, the reciprocal vectors of CNT can be derived by using the following relations

$$C_h \cdot K_1 = T \cdot K_2 = 2\pi, \quad (61)$$

$$C_h \cdot K_2 = T \cdot K_1 = 0, \quad (62)$$

Fig. 9 (A) An unrolled CNT projected onto the graphene lattice. When the CNT is rolled up in a cylinder form, the chiral vector C_h gives the circumference of cylinder and the translation vector T aligns along the cylinder axis. θ_i is chiral angle measured from the zigzag axis. In this section, we have redefine the primitive vector of graphene as $\mathbf{a}_1 = \left(\frac{\sqrt{3}}{2}a, \frac{a}{2}\right)$ and $\mathbf{a}_2 = \left(\frac{\sqrt{3}}{2}a, -\frac{a}{2}\right)$. (B) Atomic structures of (9,0) zigzag CNT (left), (5,5) armchair CNT (middle) and (8,2) chiral CNT (right). Energy band structure and corresponding DOS for (C) (9,0) zigzag CNT, (D) (10,0) zigzag CNT, (E) (5,5) armchair CNT and (F) (8,2) chiral CNT.

where the vector K_1 is the wavevector along the circumferential direction and K_2 is along the CNT axis. Explicitly, one can write as

$$K_1 = \frac{1}{N}(-t_2\mathbf{b}_1 + t_1\mathbf{b}_2), \quad (63)$$

$$K_2 = \frac{1}{N}(m\mathbf{b}_1 - n\mathbf{b}_2). \quad (64)$$

1st BZ of CNT is given as $-\frac{\pi}{T} < k \leq \frac{\pi}{T}$ along the K_2 direction.

Since $NK_1 = -t_2\mathbf{b}_1 + t_1\mathbf{b}_2$ corresponds to a reciprocal lattice vectors of graphene, two wave vectors which differ by NK_1 are equivalent. In addition, since t_1 and t_2 lack a common divisor other than unity, none of the $N-1$ vectors μK_1 ($\mu = 1, 2, \dots, N-1$) are reciprocal lattice vectors of graphene. Thus, the N wave vectors μK_1 give rise to N discrete k vectors. These arise from the quantized wave vectors associated with the periodic boundary condition due to C_h .

Therefore, the energy spectrum of CNT can be obtained by

$$E_\mu(k) = E_{2D}\left(k\frac{K_2}{|K_2|} + \mu K_1\right), \quad (65)$$

where

$$\mu = 0, 1, \dots, N-1, -\frac{\pi}{T} < k \leq \frac{\pi}{T}. \quad (66)$$

Here $E_{2D}(k_x, k_y)$ is the energy spectrum of graphene, i.e.,

$$E_{2D}(k_x, k_y) = \pm\gamma_0\sqrt{1 + 4\cos\frac{k_y a}{2}\cos\frac{\sqrt{3}k_x a}{2} + 4\cos^2\frac{k_y a}{2}}. \quad (67)$$

Note that k_x and k_y are exchanged compared with Eq. (6), because graphene lattice is rotated by 90 degree.

The N pairs of energy dispersion curves given by Eq. (65) correspond to cross-section of the two-dimensional energy dispersion surface of Eq. (67), where cuts are made along the lines of $k\frac{K_2}{|K_2|} + \mu K_1$. If such cutting line of (n, m) CNT passes through the Dirac

Fig. 10 Reciprocal space of graphene lattice. Magenta lines in the cyan rectangle represent the cutting lines for the (8,2) chiral CNT to produce the 1D energy band structure from the energy band of 2D graphene. The cutting lines are labeled by $\mu = 0, 1, 2, \dots, N-1$. $\mathbf{K}_1$ is the wavevector along the circumference of CNT and $\mathbf{K}_2$ is the wavevector along the CNT axis. The cyan rectangle is a eye guide which represents the zone having the translational invariance of the CNT. The length of $\mathbf{K}_2$ exactly corresponds to the length of 1st BZ of the CNT. $\mathbf{b}_1$ and $\mathbf{b}_2$ are the reciprocal lattice unit vectors of graphene lattice. For (8,2) chiral nanotube, $N = 28$. The cutting lines with $\mu = 6, 22$ pass through K or K' point, i.e. metallic.

K points, the energy gap between valence and conduction bands vanishes with linear dispersion. In this case, (n, m) CNT become metallic. On the other hand, if the cutting line does not pass through a K point, CNT becomes semiconducting with finite energy gap between valence and conduction bands. In Fig. 10, the cutting lines for the (8, 2) chiral CNT are shown. By collecting the N pairs of energy dispersion curves on the magenta lines, the energy band structure of the (8, 2) chiral CNT is obtained, which is shown in Fig. 9F.

In short, (n,n) armchair nanotubes are always metallic and $(n,0)$ zigzag nanotube are metallic when n is a multiple of 3. In general, (n, m) CNT becomes metallic if $n - m$ is a multiple of 3.

Conclusion

In this chapter, we provide an overview of electronic and topological properties of graphene. The low-energy electronic states of graphene near the Fermi energy are well-described by massless Dirac equation, which gives conical energy dispersion and nontrivial Berry phase. Since graphene has both time-reversal and crystal inversion symmetries, total Berry phase is zero. However, the analysis of Zak phase clarifies the existence of topological edge state at graphene zigzag edges. Also, we have presented the relation of energy spectrum between graphene and carbon nanotubes.

Abstract

Twisted bilayer graphene is a pair of graphene layers rotationally stacked with an arbitrary twist angle. The moiré interference pattern with a nanometer-scale period significantly modifies the original band structure of graphene, giving rise to a number of unusual phenomena not observed in a regular monolayer graphene. At the so-called magic angle, in particular, the energy band becomes completely flat, and superconducting phases and correlated insulating phases emerge due to the enhanced electron-electron interaction. In magnetic fields, the spectrum exhibits a fractal Hofstadter's structure due to the interference of the magnetic field and the long-range moiré periodicity. This article gives a brief overview on the electronic properties of twisted bilayer graphene mainly from the theoretical point of view.

Key points

- Twisted bilayer graphene is a pair of graphene layers stacked with a relative rotation.
- The moiré interference pattern creates a flat band in the electronic band structure.
- Superconducting phases and correlated insulating phases emerge in the flat band due to the enhanced electron-electron interaction.

Introduction

Twisted bilayer graphene (TBG) is a pair of graphene layers rotationally stacked with an arbitrary orientation. The physical property of TBG sensitively depends on the twist angle θ , which is the relative angle between lattice vectors of the individual graphene layers. When θ is small, in particular, the interference of the lattice periods gives rise to a long-period moiré beating pattern (Fig. 1a), which hybridizes the Dirac cones of single-layer graphenes into a series of moiré subbands. At the so-called magic angle, $\theta \sim 1^\circ$, the lowest subbands become almost completely flat, where unusual correlated phenomena such as superconductivity and correlated insulating states take place due to a strong enhancement of the electron-electron interaction. The discovery of TBG is followed by extensive research and development of moiré systems composed of various kind of two-dimensional materials.

Moiré pattern and moiré Brillouin zone

A TBG is composed of a pair of hexagonal lattices stacked with a relative rotation angle θ . One can define the primitive lattice vectors of layer 1 as $\mathbf{a}_1 = a(1,0)$ and $\mathbf{a}_2 = a(1/2, \sqrt{3}/2)$ with the lattice constant $a \approx 0.246$ nm, and those of the layer 2 as $\mathbf{a}'_i = R\mathbf{a}_i$ with the rotation matrix $R = R(\theta)$, as shown in Fig. 1b. Accordingly, the reciprocal lattice vectors of layer 1 are given by $\mathbf{b}_1 = (2\pi/a)(1, -1/\sqrt{3})$ and $\mathbf{b}_2 = (2\pi/a)(0, 2/\sqrt{3})$, layer 2 by $\mathbf{b}'_i = R\mathbf{b}_i$.

In small $\theta \ll 1$, the interference of the lattice periods in the two layers gives rise to a moiré pattern with a period much greater than the atomic scale (Fig. 1a). The reciprocal lattice vectors for the moiré pattern are given by

$$\mathbf{G}_i^M = \mathbf{b}_i - \mathbf{b}'_i = (1 - R)\mathbf{b}_i \quad (i = 1, 2). \quad (1)$$

The corresponding lattice vectors in the real space, $\mathbf{L}_i^M$, are defined by $\mathbf{L}_i^M \cdot \mathbf{G}_j^M = 2\pi\delta_{ij}$. As a result, the moiré period $L_M \equiv |\mathbf{L}_i^M|$ becomes

$$L_M = \frac{a}{2 \sin(\theta/2)} \approx a/\theta. \quad (2)$$

Fig. 1 (a) Atomic structures of TBG with different twist angles. (b) The lattice vectors and sublattices in TBG. (c) The detailed atomic structure at $\theta = 2.65^\circ$. The local structure resembles a non-rotated bilayer such as AA, AB, BA-stacking (see the text).

In decreasing θ , the moiré period L_M increases in inversely proportional to θ . At the magic angle ($\theta \sim 1^\circ$), L_M is about 14 nm, where the unit cell includes more than 10,000 atoms. Fig. 1c shows a detailed atomic structure at $\theta = 2.65^\circ$. The local structure resembles a non-rotated bilayer such as AA, AB, BA-stacking, and it slowly varies as a function of position. Here AA-stacking refers to a configuration where A-site of layer 1 is located just above A-site of layer 2, and therefore the honey-comb lattices completely overlap. The AB-stacking is the graphite's structure, where A is just above B. The BA-stacking is just a 180° rotation of the AB-stacking.

The Dirac points (the band touching points) of each graphene layer are located at the Brillouin zone corners K_+ and K_- (referred to as valleys), where $\mathbf{K}_\xi = -\xi(2\mathbf{b}_1 + \mathbf{b}_2)/3$ for layer 1 and $\mathbf{K}_\xi' = R\mathbf{K}_\xi$ for layer 2. In TBG, $\mathbf{K}_\xi$ ($\xi = \pm$) of layer 1 and 2 are displaced by

$$\Delta K = 2K \sin(\theta/2) \approx K\theta, \quad (3)$$

where $K = 4\pi/(3a)$ is the distance from the origin to $K_\pm$. The moiré-Brillouin zone (superlattice Brillouin zone spanned by $\mathbf{G}_i^M$) becomes a small hexagon with side length of ΔK as shown in Fig. 2. The zone tiling pattern near K_+ and that near K_- are not generally consistent with each other, and this corresponds to the fact that the moiré pattern is not generally commensurate with the atomic period of graphene, i.e., the system does not have an exact translational symmetry as a whole. The electronic states of K_+ and those of K_- are hardly hybridized when the moiré period is sufficiently larger than the atomic period (equivalent with $K \gg \Delta K$), so one can treat these distant valleys as independent subsystems.

Effective continuum model

When the twist angle θ is small, the electronic band structure of TBG is well described by a long-range effective theory. The effective Hamiltonian for valley $\xi = \pm$ is obtained by extracting the matrix elements near $\mathbf{K}_\xi$ with small wave-number shift (Bistritzer and MacDonald, 2011a; Lopes dos Santos et al., 2007). It is given by a 4×4 matrix,

$$\mathcal{H} = \begin{pmatrix} H_0 & U^\dagger(\mathbf{r}) \\ U(\mathbf{r}) & H_0 \end{pmatrix}, \quad (4)$$

Fig. 2 Brillouin zone (BZ) folding in TBG. Large hexagons represent the BZ of graphene layer 1 and 2, and small ones are the moiré BZ.

where

$$H_0 = -\hbar v \begin{pmatrix} 0 & \xi k_x - i k_y \\ \xi k_x + i k_y & 0 \end{pmatrix}, \quad (5)$$

$$U(\mathbf{r}) = \sum_{j=0,1,2} e^{i\xi \Delta \mathbf{K}_j \cdot \mathbf{r}} \begin{pmatrix} t & t' e^{-i\frac{2\pi j}{3}} \\ t' e^{i\frac{2\pi j}{3}} & t \end{pmatrix}. \quad (6)$$

The Hamiltonian works on a four-component wave-function $(\psi_{A_1}, \psi_{B_1}, \psi_{A_2}, \psi_{B_2})$ where ψ_{A_1} stands for the wavefunction on sublattice A of layer 1, etc. H_0 is the Dirac Hamiltonian of the monolayer graphene. $U(\mathbf{r})$ is the moiré interlayer coupling, where

$$\Delta \mathbf{K}_j = \Delta K (-\sin(2\pi j/3), \cos(2\pi j/3)) \quad (7)$$

for $j = 0, 1, 2$ is a triplet of 120° rotated vectors, which connect the Dirac points of layer 1 and 2. Here t, t' represent the coupling strength of AA-stacking and AB-stacking regions, respectively. In the rigid graphene model assuming perfect honeycomb lattices for graphene layers, one has $t = t' \sim 0.1$ eV. In real systems, the honeycomb lattices are relaxed to optimize the interlayer stacking energy, and the effect can be incorporated as a difference between t and t' ($t < t'$) (Koshino et al., 2018).

The physical meaning of $U(\mathbf{r})$ is clearly seen when one considers the matrix U at a specific $\mathbf{r}$ point. At $\mathbf{r} = 0$, for instance, the diagonal components of U become $3t$ while the off-diagonal ones are zero. This corresponds to the AA stacking region (Fig. 1c), where the A_1 and A_2 (also B_1 and B_2) are vertically aligned and strongly coupled. At AB-stacking position, on the other hand, A_1 and B_2 are vertically aligned giving an off-diagonal element $3t'$, while other three elements vanish.

The biggest advantage of the effective continuum model is that one can obtain band structure in any small twist angles regardless of the commensurability of the exact lattice structure. When the rotation angle is relatively large ($>20^\circ$) and the moiré period becomes the atomic scale, however, the long-range effective theory is not applicable anymore, and the system becomes essentially quasiperiodic in that incommensurate periodicities coexist. In particular, the 30-degree rotated TBG has a feature of 12-fold rotational symmetric quasicrystal, which is intimately related to a quasiperiodic tiling in mathematics. The 30-degree TBG was experimentally fabricated by an epitaxial growth on silicon-carbide surface (Ahn et al., 2018; Moon et al., 2019).

Band structure

Fig. 3 shows an example of the band calculation for TBGs with some twist angles (Nam and Koshino, 2017), where κ, γ, μ and κ' in the horizontal axis represent the symmetric points in the moiré Brillouin zone in Fig. 2. The black solid curve and the red dashed curve represent the energy bands with and without the lattice relaxation, which is important in the small angle regime $\theta < 2^\circ$. In $\theta = 2.65$ (Fig. 3a), the linear band at κ, κ' are remnants of the Dirac cones of monolayer graphene. In decreasing the twist angle, the band velocity of the Dirac cone is significantly reduced, and nearly flat bands emerge at $\sim 1^\circ$, which is called the magic

Fig. 3 Band calculation for TBGs with different twist angles. The label κ , γ , μ and κ' represent the symmetric points in the moiré Brillouin zone (Fig. 2). The black solid curves and the red dashed curves, respectively, are the energy bands with and without the lattice relaxation. From Ref. Nam NNT and Koshino M (2017) Lattice relaxation and energy band modulation in twisted bilayer graphene. *Physical Review B* 96(7): 075311. Errata: *Phys. Rev. B* 101: 099901 (2020).

angle (Bistritzer and MacDonald, 2011a). There are two flat bands in each spin/valley sector, and hence eight flat bands in total. The number of electrons accommodated in a single flat band (i.e., per spin and valley) is given by $n_0 = 1/S_M$, where $S_M = (\sqrt{3}/2)L_M^2$ is the area of the moiré unit cell. The lattice relaxation effect opens energy gaps between the flat bands and excited bands. When θ is further decreased beyond the magic angle, the band width is broadened again, and the band structure changes in a complex manner.

The reduction of the band velocity and the formation of the moiré subband can be understood by the following argument. Fig. 4a shows the hybridization of the Dirac cones of monolayers. The layer 1's cone at the center is hybridized with layer 2's cones shifted by ΔK_j 's in Eq. (7). A band anti-crossing occurs at intersections of the cones, as schematically illustrated in Fig. 4b. The system has two characteristic energy scales: the interlayer hopping energy t (or t') ~ 0.1 meV, which determines the gap width in the anti-crossing, and $\hbar v \Delta K \propto \theta$, which is the energy distance between the Dirac point and the band crossing point. The structure of the moiré subband is determined by the relative magnitude of t to $\hbar v \Delta K$. When $\theta > 5^\circ$, one has $t \ll \hbar v \Delta K$ so that the interlayer hopping can be treated as a perturbation for the Dirac cone, giving a small gap at the intersection. In decreasing θ , the ratio $t/(\hbar v \Delta K)$ increases in inversely proportional to θ , and it exceeds 1 at $\theta < 1^\circ$. This is a strong coupling regime, where the interlayer coupling completely reconstructs the Dirac cone into a series of the moiré subbands.

An extreme model with $t \rightarrow 0$ is called the chiral limit, as the Hamiltonian becomes chiral symmetric (Tarnopolsky et al., 2019). There the lowest energy bands are shown to be exactly flat at a series of angles and the magic angle argued above ($\theta \sim 1^\circ$) corresponds to the greatest one in the series.

Superconductivity and correlated phenomena

The flat band in the magic angle TBG is expected to be a strongly correlated system governed by the electron-electron interaction, since the kinetic energy (band energy) is quenched. Indeed, it was found that TBG samples near 1° exhibit the superconductivity in the low temperature around 1 K (Cao et al., 2018a, 2018b). The superconducting state is highly sensitive to the twist angle, suggesting that the phenomena is related to the band flatness.

Fig. 5 is the schematic phase diagram of the magic angle TBG, where the horizontal axis represents the electron density in units of n_0 (the number of electrons per a moiré band) and the vertical axis is temperature. The flat band region corresponds to $-4 \leq n/n_0 \leq 4$, where the $n = 0$ is the charge neutral point. In Fig. 5, thick strips at $n/n_0 = \pm 4$ represent the band insulator phases, where the Fermi energy is located in the band gap above / below the flat bands. In decreasing the temperature, one sees extra insulating phases at $n/n_0 = \pm 2$ due to the electron-electron interaction, which are called the correlated insulating (CI) phases. The superconducting phase emerges by slightly doping carriers to the CI phases. Experimentally, the phase diagram is obtained just from a single TBG sample by controlling the charge density by the gate electric field effect. This is in contrast to 3D materials, where changing carrier density requires chemical doping.

It was reported that some TBG samples exhibit insulating phases also at the odd fillings $n/n_0 = \pm 1, \pm 3$ (Yankowitz et al., 2019), and superconducting phases nearby (Lu et al., 2019). The ferromagnetism and anomalous Hall effect were also reported at $n/n_0 = 3$ (Serlin et al., 2020; Sharpe et al., 2019). The detailed structure of the phase diagram, particularly at the odd filling, is highly dependent on samples, presumably due to the non-uniformity of the moiré stacking structure and also the effect of the substrate under the TBG.

The mechanism of the superconductivity and correlated insulating states in TBG is still under debate. The insulating behavior at the integer filling suggests an analogy to the quantum Hall ferromagnetism where the spin/valley degenerate Landau levels spontaneously split under electron-electron interaction. Various many-body states, such as the inter valley coherent states, were also proposed as possible candidates of the ground states in the magic angle TBG (Bultinck et al., 2020).

The superconductivity and correlated phases were also found in other moiré graphene systems, such as twisted double bilayer graphene (i.e., twisted pair of Bernal bilayer graphenes) (Cao et al., 2019; Liu et al., 2019; Shen et al., 2020) and twisted trilayer graphene (Hao et al., 2021; Lin et al., 2020; Park et al., 2021; Zhu et al., 2020), where the band flatness is supposed to be essential as in TBG.

Magneto spectra and quantum hall effect

In strong magnetic fields, the energy spectrum of TBG exhibits a fractal gap structure called Hofstadter's butterfly (Bistritzer and MacDonald, 2011b; Moon and Koshino, 2012). The Hofstadter spectrum generally occurs in two dimensional systems subject to both magnetic field and periodic electrostatic potential (Hofstadter, 1976), where the fractal gap structure is observed when the magnetic length $\sqrt{\hbar/(eB)}$ and the potential period are comparable. While conventional atomic lattices with periodicities of less than 1 nm require unfeasibly large magnetic fields ($B > 10,000$ Tesla) to reach this condition, the TBG with a periodic modulation of the order of 10 nm enables experimental access to the fractal spectrum at a few 10 Tesla.

Fig. 6 shows an example of Hofstadter's spectrum calculated for TBG of $\theta = 2.65^\circ$ (Moon and Koshino, 2012). The left panel, Fig. 6a presents the energy spectrum plotted against the magnetic field amplitude, where the black part indicates the energy regions where electron states exist, and the white part is energy gap. The middle panel (b) shows the same spectrum, but with color and number inside each gap indicating the quantized Hall conductivity when the Fermi energy lies in the gap. The right-most panel (c) is the zero-field band structure in the same energy range. In Fig. 6a, the spectrum is characterized by the number of magnetic field

Fig. 5 Schematic phase diagram of the magic angle TBG, against the electron density and temperature. CI stands for correlated insulating phase, and SC stands for superconducting phase. Vertical dashed lines indicate correlated insulating phases at the odd fillings observed in some experiments.

Fig. 6 (a) Energy spectrum plotted against the magnetic field calculated for TBG of $\theta = 2.65^\circ$. The black and white regions indicate energy bands and energy gaps, respectively. (b) The same spectrum, but with color and number inside each gap indicating the quantized Hall conductivity. (c) Corresponding band structure at zero magnetic field. $\bar{K}, \bar{\Gamma}, \bar{M}, \bar{K}'$ correspond to $\kappa, \gamma, \mu, \kappa'$ in Fig. 2, respectively. From Ref. Moon P and Koshino M (2012) Energy spectrum and quantum hall effect in twisted bilayer graphene. *Physical Review B* 85: 195458.

quanta per a moiré unit cell, Φ/Φ_0 , where $\Phi = BS_M$ is the magnetic flux penetrating the moiré unit area S_M , and $\Phi_0 = h/e$ is the magnetic flux quantum. The quantized Hall conductivity in the mini-gaps behaves non-monotonically as a function of Fermi energy, as usually expected in the Hofstadter butterfly. The recursive gap structure was first observed experimentally in the moiré superlattice of graphene on hexagonal-boron-nitride (hBN) (Dean et al., 2013; Hunt et al., 2013; Ponomarenko et al., 2013).

Conclusion

The electronic properties of TBG were briefly reviewed. It was shown that the moiré period, of typically a few to tens of nanometer, significantly modifies the original band structure of graphene, giving rise to a number of unusual phenomena not observed without the moiré stacking. The energy width of the moiré subbands decreases as the twist angle is reduced, and dispersionless flat bands appear at the magic angle near 1° , where superconducting phases and correlated insulating phases emerge due to the electron-electron interaction. In magnetic fields, the spectrum exhibits a fractal Hofstadter's structure due to the interference of the magnetic field and the long-range moiré periodicity.

The discovery of TBG is followed by extensive research of various moiré superlattices other than graphenes. For instance, a twisted stack of transition metal dichalcogenide (e.g., MoS_2 , WS_2 , WSe_2 , etc.) is a moiré superlattice with unusual optical properties, where an optical excitation gives rise to localized excitons trapped to the moiré pattern (Jin et al., 2019; Seyler et al., 2019; Tran et al., 2019). The search for novel physics in twisted systems is extended to a wide variety of two-dimensional systems, including magnetic and superconducting 2D materials and topological insulators.

Abstract

We describe transport properties of graphene and related experiments. The main source of carrier scattering in graphene is charged impurities at low temperatures. This leads to the linear relationship between the conductivity and the carrier density. High-mobility graphene devices also exhibit unique ballistic transport such as the Klein tunneling. At high temperatures, electron-electron scattering becomes significant in clean graphene devices, and carriers behave as fluids. Topological valley transport also occurs in graphene when the inversion symmetry is broken. The topological valley current has been detected in nonlocal transport experiments.

Key points

- Charged impurity scattering, ballistic transport, topological transport, nonlocal transport, hydrodynamic transport.

Introduction

Graphene is a monolayer of carbon atoms in a honeycomb lattice. Its properties had been theoretically investigated already before its discovery, but monolayer had been thought to be too unstable to exist. In 2004, it was shown by Novoselov, Geim, and coworkers that it is possible to exfoliate a monolayer graphene flake from graphite by a scotch tape and transfer it onto a SiO₂ substrate (Novoselov et al., 2004). It also became possible to measure the electrical conductivity of graphene by depositing contact metal electrodes on exfoliated graphene flakes. Owing to the unique combination of physical properties of graphene such as high mobility, high transparency, relativistic natures, great mechanical strength, large thermal conductivity, etc., intense studies have been conducted for revealing the electronic properties of graphene by electrical transport experiments.

Graphene on SiO₂ has high carrier mobility exceeding 10,000 cm²/Vs. The main source of scattering for carriers in graphene is the charged impurities attached during the fabrication process. By annealing the graphene devices, influence of the charged impurities can be suppressed to some extent. Temperature dependence of the conductivity also revealed influence of scattering by phonons. Graphene devices display ballistic transport properties when the device dimension becomes submicron scale at relatively low temperatures. The quantum Hall effect is also observed for graphene on SiO₂ owing to its high mobility (Novoselov et al., 2005; Zhang et al., 2005). The high quality of graphene layers also enabled identification of the band structure of few-layer graphene (Craciun et al., 2011).

Several years after the discovery of graphene, even higher-quality graphene devices suffering less from charge disorder than those on SiO₂ became available by using a suspended graphene and current annealing (Du et al., 2008; Bolotin et al., 2008). The development of layer-by-layer transfer technique has also allowed for stacking different layered materials while precisely tuning their relative angles. When graphene is encapsulated by an atomically flat insulator, hexagonal boron nitride (h-BN) flakes, prepared high-quality graphene devices become stable (Dean et al., 2010). Once graphene is encapsulated, further contamination is avoided. Electrical contacts to graphene are taken by the “edge contacts.” The transport properties of graphene became able to be measured more reproducibly and intrinsic properties of graphene that can be found only in high-quality devices have been investigated. The mobility of suspended or encapsulated graphene exceeds 100,000 cm²/Vs.

Even in high-quality graphene, charge disorder is still one of the main sources of carrier scattering at low temperatures. In a clean graphene device at high temperatures, the electron-electron scattering length can become smaller than the mean free path and electron-phonon scattering length. The carrier transport then obeys hydrodynamics. The viscosity of graphene induced by strong electron-electron interaction is indeed larger than those of standard semiconductors such as the high electron mobility transistor (HEMT) of a GaAs/AlGaAs heterostructure.

When the symmetry of graphene is broken, topological transport associated with the valley contrasting intrinsic Hall conductivity occurs. The symmetry breaking is induced by aligning relative angle between graphene and h-BN such that graphene is affected by the potential from boron and nitrogen atoms, or by applying a perpendicular electric field to a few-layer graphene. For an encapsulated few-layer graphene, one can independently control the carrier density and perpendicular electric field by the top gate and back gate through h-BN layers.

Owing to above-mentioned unique properties, graphene attracts considerable attention. In addition, because graphene appears on the surface and can constitute a “van der Waals heterostructure” (Geim and Grigorieva, 2013), it can be combined with various materials in novel functional devices.

Overview

In this article, we mainly focus on transport properties of pristine monolayer and bilayer graphene observed in real graphene devices. While graphene can be combined with other various materials in van der Waals heterostructures and be used for spintronics and superconducting device applications, externally induced properties are out of scope in this article. The quantum Hall effect in graphene is also discussed in the other articles of this encyclopedia (Zhang, 2023; McCann, 2006, 2023).

We start with description of the intrinsic electronic structure of graphene and discuss corresponding transport properties. We then discuss carrier scatterings in graphene mostly dominated by charged impurities. We also discuss ballistic transport, where device dimension is smaller than or comparable with the mean free path. We then move to the nonlocal transport that is used to detect the topological transport in real graphene devices. Finally, we describe experimental observations of hydrodynamic transport dominated by the electron-electron scattering in graphene devices.

Electronic structures of graphene

Monolayer graphene is a zero-gap semiconductor. Energy band of graphene can be calculated using a tight banding model for the honeycomb lattice (Wallace, 1947; Castro Neto et al., 2009). The unit cell consists of two carbon atoms A and B, forming two sublattices. We only consider the nearest neighbor hopping in the first approximation. It is straightforward to derive effective Hamiltonians for the two energetically degenerate but nonequivalent valleys K and K'

$$H_K = \hbar v_F \begin{pmatrix} 0 & k_x - ik_y \\ k_x + ik_y & 0 \end{pmatrix}$$

$$H_{K'} = -\hbar v_F \begin{pmatrix} 0 & k_x + ik_y \\ k_x - ik_y & 0 \end{pmatrix}$$

operating on $(|A\rangle, |B\rangle)^T$, where $|A\rangle$ and $|B\rangle$ are, respectively, Bloch wave function components on the A and B sublattices, $\mathbf{k} = (k_x, k_y)$ is the wave vector measured from the valley center, $\hbar$ is Planck constant divided by 2π , and $v_F \sim 1 \times 10^6$ m²/s is the velocity of carriers. Using Pauli matrices, we can rewrite it as

$$H^{\text{MLG}} = \hbar v_F (\tau_z k_x \sigma_x + k_y \sigma_y), \quad (1)$$

where τ_z is the valley index, i.e., $\tau_z = 1$ for valley K and $\tau_z = -1$ for valley K'.

This Hamiltonian leads to the linear dispersion

$$\varepsilon(\mathbf{k}) = \pm \hbar v_F k \quad (2)$$

implying that carriers in graphene are massless with the energy independent velocity v_F . Here the + and – denotes those of electrons and holes. The $\varepsilon(\mathbf{k}) = 0$ point is termed the Dirac point or the charge neutrality point because the carrier density $n = n_e - n_h$ defined by the density n_e and n_h of electrons and holes becomes zero. Eq. (4) also indicates that the pseudospin defined by the presence of an electron in either of the sublattices and the wave vector $\mathbf{k}$ are coupled. In the absence of atomic-scale short-range scattering, pseudospin should be conserved. This prohibits backscattering of electrons because flip of $\mathbf{k}$ direction should accompany flip of the pseudospin. This suggests that the backscattering is suppressed near zero energy in the absence of short-range scattering induced by lattice defects. When $\mathbf{k}$ rotates once in the xy-plane, the pseudospin also rotates once. This leads to the Berry phase of π at K valley and $-\pi$ at K' valley.

In AB-staked bilayer graphene, there are four atoms in the unit cell labeled as A1, B1, A2, and B2. A1 and B1 are on the bottom layer and A2 and B2 are on the top layer. There is a vertical hopping γ between A2 and B1. The effective Hamiltonian is expressed as a 4×4 matrix

$$H = \begin{pmatrix} 0 & 0 \\ H^{\text{MLG}} & -\gamma & 0 \\ 0 & -\gamma & H^{\text{MLG}} \\ 0 & 0 & 0 \end{pmatrix}$$

where H^{MLG} is the effective Hamiltonian for monolayer graphene (Eq. 1). For the small energy $|\varepsilon(\mathbf{k})| \ll \gamma$, this Hamiltonian can be reduced into the two-band Hamiltonian for the $(|A1\rangle, |B2\rangle)^T$ basis as

$$H_K = \frac{\hbar^2}{2m_{\text{BL}}} \begin{pmatrix} 0 & (k_x - ik_y)^2 \\ (k_x + ik_y)^2 & 0 \end{pmatrix}$$

$$H_{K'} = -\frac{\hbar^2}{2m_{\text{BL}}} \begin{pmatrix} 0 & (k_x + ik_y)^2 \\ (k_x - ik_y)^2 & 0 \end{pmatrix}$$

where $m_{\text{BL}} = \gamma/(2v_F^2)$ is the effective mass of the bilayer graphene (McCann, 2006, 2023). The low energy bands are parabolic that touch each other at zero energy. Using the azimuthal angle ϕ of $\mathbf{k}$ and $k^2 = k_x^2 + k_y^2$, the effective Hamiltonian is rewritten as

$$H^{\text{BLG}} = \frac{\hbar^2 k^2}{2m_{\text{BL}}} (\cos(2\phi)\sigma_x + \tau_v \sin(2\phi)\sigma_y). \quad (3)$$

This Hamiltonian indicates the Berry phase 2π at K valley and -2π at K' valley.

The band structure of thicker N-layer graphene ($N > 2$) depends on the stacking. ABC-stacked N-layer graphene has k^N dispersion and Berry phase $N\pi$. ABA-stacked multilayer graphene consists of monolayer-like (linear) band and bilayer-like (parabolic) bands. The monolayer-like band exists only for odd N . These bands as well as the Berry phase can be experimentally identified by the measurement of the quantum Hall effect (Zhang, 2023; McCann, 2006, 2023).

While both monolayer and bilayer graphene are zero-gap semiconductors, the band gap can be induced by breaking the inversion symmetry. When there is a potential difference 2Δ between A and B sites of monolayer graphene, the mass term $\Delta\sigma_z$ is added to the effective Hamiltonian. The effective Hamiltonian becomes

$$H^{\text{MLG}} = \hbar v_F (\tau_z k_x \sigma_x + k_y \sigma_y) + \Delta \sigma_z. \quad (4)$$

This results in nonlinear bands

$$\varepsilon(\mathbf{k}) = \pm \sqrt{(\hbar v_F k)^2 + \Delta^2}$$

and the effective mass $m^* = \Delta/v_F^2$ at the band bottom.

For bilayer graphene, when there is a potential difference 2Δ between A1 and B2 sites, the effective Hamiltonian becomes

$$H^{\text{BLG}} = \frac{\hbar^2 k^2}{2m_{\text{BL}}} (\cos(2\phi)\sigma_x + \tau_v \sin(2\phi)\sigma_y) + \Delta \sigma_z. \quad (5)$$

This results in the non-parabolic bands $\varepsilon(\mathbf{k}) = \pm \sqrt{\left(\frac{\hbar^2 k^2}{2m_{\text{BL}}}\right)^2 + \Delta^2}$ with the gap opening by 2Δ . The advantage of bilayer graphene is that this gap can be induced by the application of a perpendicular electric field D that introduces the potential difference between the two layers. We readily expect insulating behavior at the charge neutrality $n = 0$ in the presence of D for bilayer graphene. This also applies to ABC-stacked multilayer graphene.

Topological properties

The effective Hamiltonian of massive graphene in Eqs. (4) and (5) leads to non-zero Berry curvature for $\Delta \neq 0$ (Xiao et al., 2007). The Berry curvature is defined as

$$\mathbf{\Omega}(\mathbf{k}) = i\nabla_{\mathbf{k}} \times \langle u(\mathbf{k}) | \nabla_{\mathbf{k}} u(\mathbf{k}) \rangle, \quad (6)$$

using the Fourier transformation $u(\mathbf{k})$ of the periodic part of the Bloch function. Since the Berry phase is given by the integral of $i\langle u(\mathbf{k}) | \nabla_{\mathbf{k}} u(\mathbf{k}) \rangle$ along a closed loop in the momentum space, $\mathbf{\Omega}(\mathbf{k})$ corresponds to the magnetic flux density in the momentum space. This is in analogy with the Aharonov-Bohm phase given by the integral of the vector potential $\mathbf{A}$ along a closed loop in the real space, and the magnetic flux density defined by $\mathbf{B}(\mathbf{r}) = \nabla_{\mathbf{r}} \times \mathbf{A}(\mathbf{r})$. Indeed, the role of $\mathbf{\Omega}(\mathbf{k})$ in the semi-classical dynamics in the Bloch bands is understood as a correction to the group velocity $\mathbf{v} = \dot{\mathbf{r}} = \frac{\partial \varepsilon(\mathbf{k})}{\hbar \partial \mathbf{k}}$ in the presence of an in-plane electric field $\mathbf{E}$:

$$\dot{\mathbf{r}} = \frac{\partial \varepsilon(\mathbf{k})}{\hbar \partial \mathbf{k}} + \dot{\mathbf{k}} \times \boldsymbol{\Omega}(\mathbf{k}). \quad (7)$$

We see that $\boldsymbol{\Omega}(\mathbf{k})$ works as a magnetic flux density in the momentum space by comparing Eq. (7) with $\hbar \dot{\mathbf{k}} = -e\mathbf{E} - e\dot{\mathbf{r}} \times \mathbf{B}$. The second term in Eq. (7) driven by $\mathbf{E} = -\frac{\hbar}{e}\dot{\mathbf{k}}$ is called anomalous velocity:

$$\mathbf{v}_A = -\frac{e}{\hbar} \mathbf{E} \times \boldsymbol{\Omega}(\mathbf{k}). \quad (8)$$

This term leads to the intrinsic Hall conductivity:

$$\sigma_H^{\text{int}} = g_s \frac{e^2}{\hbar} \int \frac{d^2 k}{(2\pi)^2} f(\mathbf{k}) \Omega(\mathbf{k}), \quad (9)$$

where g_s is the spin degeneracy (usually $g_s = 2$), $\Omega(\mathbf{k})$ is the z-component of the Berry curvature, and $f(\mathbf{k})$ is the Fermi-Dirac distribution function. It is straightforward to derive the Berry curvature for the two-level system represented in Eqs. (4) and (5).

For massive monolayer graphene, the Berry curvature is

$$\Omega(\mathbf{k}) = \tau_z \frac{\gamma^2 \Delta}{2\varepsilon(\mathbf{k})^3}, \quad (10)$$

which becomes maximum or minimum at K and K' point. This leads to the valley-dependent intrinsic Hall effect for low energy carriers. Energy dependence of the intrinsic valley Hall conductivity defined as $\sigma_{xy}^v \equiv \sigma_H^{\text{int},K} - \sigma_H^{\text{int},K'}$ becomes

$$\sigma_{xy}^v(\varepsilon) \equiv \sigma_H^{\text{int},K} - \sigma_H^{\text{int},K'} = \begin{cases} \frac{2e^2}{\hbar} \frac{\Delta}{|\varepsilon|} (|\varepsilon| > \Delta) \\ \frac{2e^2}{\hbar} (|\varepsilon| < \Delta) \end{cases} \quad (11)$$

at zero temperature. In analogy with the spin Hall effect, where spin current is induced in the transverse direction to the injected charge current, valley current is induced by an applied in-plane electric field $\mathbf{E}$ to the transverse direction. This phenomenon is called valley Hall effect. σ_{xy}^v corresponds to the conversion ratio between the induced valley current density and $\mathbf{E}$.

For bilayer graphene, the Berry curvature and the zero-temperature valley Hall conductivity become

$$\Omega(\mathbf{k}) = \tau_z \frac{\hbar^2}{m^*} \frac{\Delta \sqrt{\varepsilon(\mathbf{k})^2 - \Delta^2}}{\varepsilon(\mathbf{k})^3} \quad (12)$$

$$\sigma_{xy}^v(\varepsilon) = \begin{cases} \frac{4e^2}{\hbar} \frac{\Delta}{|\varepsilon|} (|\varepsilon| > \Delta) \\ \frac{4e^2}{\hbar} (|\varepsilon| < \Delta) \end{cases} \quad (13)$$

with Δ tuned by the perpendicular electric field.

Carrier scattering in graphene devices

A typical graphene device is supported by a substrate. Graphene is capacitively coupled with a gate electrode (usually a back gate) that can be used to tune the carrier density n . In some devices, graphene is sandwiched by the back gate and top gate through insulating layers. In such a dual-gated device, the carrier density n and the perpendicular electric field D can be independently controlled. This dual-gated structure is useful to control the electronic state of bilayer graphene. By depositing metal electrodes on graphene, one can measure the electrical transport through graphene. The electrical contact is realized with various metals such as Cu, Ag, Au, Ni, and Pd (Giubileo and Di Bartolomeo, 2017). The deposited metal dopes carriers in the region beneath the metal, allowing the electron transport between the metal and graphene. Transfer length or the effective length of the contact region is of the order of micron. The contact resistance usually depends on the length of the deposited metal contact rather than its area. Electrical contacts can also be taken to the edges of graphene. Even though the improvement of the electrical contact is still an important issue, the contact resistance (typically order of 100 $\Omega\mu\text{m}$) is usually smaller than the resistance of graphene itself in a wide range of temperature. Therefore, the electrical conductance of graphene can be measured precisely as a function of n using a graphene field effect transistor like device and sweeping the gate voltage.

Because monolayer graphene has the linear dispersion, the carrier density is proportional to the energy squared $n = \frac{g_s g_v \varepsilon^2}{4\pi \hbar^2 v_F^2}$, where $g_s = 2$ and $g_v = 2$ are the spin degeneracy and valley degeneracy, respectively. The density of states $D(\varepsilon) = dn/d\varepsilon$ is proportional to ε . If the scattering probability $\hbar/\tau_m(\varepsilon)$ is proportional to $D(\varepsilon) \propto \varepsilon$ of the final state, the momentum relaxation time $\tau_m(\varepsilon)$ is proportional to ε^{-1} . Therefore, the electrical conductivity $\sigma = e^2 D(\varepsilon_F) \left(\frac{v_F^2 \tau_m(\varepsilon_F)}{2} \right) \propto D(\varepsilon_F) \tau_m(\varepsilon_F)$ should be energy and density

Fig. 1 Typical conductivity of graphene as a function of the back gate voltage. Inset shows a typical device on a SiO₂ substrate. Adopted from Castro Neto AH, et al. (2009) The electronic properties of graphene. *Reviews of Modern Physics* 81: 109.

independent (Shon and Ando, 1998). Despite this initial expectation, σ is proportional to n at relatively low temperatures in experiments (see Fig. 1) (Novoselov et al., 2005; Das Sarma et al., 2011; Castro Neto et al., 2009).

This n -linear dependence of σ is assigned to the scattering by charged impurities. For the δ -function-like scattering with the potential extension smaller than the wavelength $\lambda = 2\pi/k$, the scattering probability is proportional to ε . However, it is proportional to ε^{-1} for long-range scattering, leading to $\sigma \propto \varepsilon^2 \propto n$, as we will discuss in the following.

We consider carrier transport in the Boltzmann formalism by linear response of the distribution function $f_k = f_0 + \delta f_k$ to the in-plane electric field E , where f_0 is the Fermi distribution function and δf_k is the E linear term. The scattering probability

$$W(\mathbf{k}', \mathbf{k}) = \frac{2\pi}{\hbar} \langle |V_{\mathbf{k}', \mathbf{k}}|^2 \rangle \delta(\varepsilon(\mathbf{k}) - \varepsilon(\mathbf{k}')) \quad (14)$$

between the initial and final wave vectors $\mathbf{k}$ and $\mathbf{k}'$ is determined by the matrix element $V_{\mathbf{k}', \mathbf{k}}$ of the scattering potential and its squared average $\langle |V_{\mathbf{k}', \mathbf{k}}|^2 \rangle$ over the scatterers' configurations. The solution becomes

$$\delta f_k = e\tau_m(\varepsilon_k) \frac{\partial f_0}{\partial \varepsilon_k} \mathbf{v} \cdot \mathbf{E} \quad (15)$$

with the relaxation time given by

$$\frac{1}{\tau_m(\varepsilon_k)} = \int \frac{d\mathbf{k}'}{(2\pi)^2} (1 - \cos \theta_{\mathbf{k}, \mathbf{k}'}) W(\mathbf{k}', \mathbf{k}), \quad (16)$$

where $\theta_{\mathbf{k}, \mathbf{k}'}$ is the scattering angle. For randomly distributed scatters with identical potential shape $V(\mathbf{r} - \mathbf{r}_i)$ and density n_i , the matrix element term becomes

$$\langle |V_{\mathbf{k}', \mathbf{k}}|^2 \rangle = n_i |V(\mathbf{k}' - \mathbf{k})|^2 F(\mathbf{k}' - \mathbf{k}), \quad (17)$$

where $V(\mathbf{q})$ is the Fourier transform of $V(\mathbf{r})$ and $F(\mathbf{k}' - \mathbf{k}) = (1 + \cos \theta_{\mathbf{k}, \mathbf{k}'})/2$ is the form factor associated with the inner product of the wave functions of the initial and final states. From Eqs. (14) and (16), we obtain the relaxation time as

$$\frac{1}{\tau_m(\varepsilon_k)} = \frac{n_i}{\hbar} \frac{|\varepsilon|}{(\hbar v_F)^2} \int_0^\pi \frac{d\theta}{2\pi} (1 - \cos^2 \theta) \langle |V(\mathbf{q})|^2 \rangle \quad (18)$$

with $\mathbf{q} = \mathbf{k}' - \mathbf{k}$. Here, $\langle |V(\mathbf{q})|^2 \rangle = |V(\mathbf{q})|^2$ with $q = 2k \sin(\theta/2)$. In Eq. (18), $(1 - \cos^2 \theta)$ term originating from $F(\mathbf{k}' - \mathbf{k})$ indicates suppression of the backscattering or large-angle scattering near $\theta = \pi$. This is unique in graphene and related with the coupling of $\mathbf{k}$ and pseudospin (sublattice degree of freedom) as we have discussed for Eq. (1).

For the short-range (δ -function-like) scattering, $V(q)$ becomes q -independent and is replaced with a constant. Eq. (18) leads to $\frac{1}{\tau_m(\varepsilon)} \propto |\varepsilon|$ and σ being independent of n . For real devices, however, we need to consider the screening effect to discuss the Coulomb scattering. Following the representation in Ando et al. (1982), the screened potential of the charged impurity is given by

$$V(q) = \frac{2\pi e^2}{\kappa q \varepsilon(q)}, \quad (19)$$

where κ is the effective dielectric constant determined by the system environment and $\varepsilon(q)$ is determined by the screening by electrons in graphene. The screening effect is represented by the polarization function $\Pi(q)$ defined as

$$\varepsilon(q) = 1 + \frac{2\pi e^2}{\kappa q} \Pi(q). \quad (20)$$

$\Pi(q)$ at zero temperature becomes constant for $q < 2k_F$ and is simply replaced with the density of states $D(\varepsilon_F)$ (Ando, 2006; Hwang and Das Sarma, 2007). Therefore, at low enough temperature, the Thomas-Fermi approximation holds with the constant screening constant q_s as

$$V(q) = \frac{2\pi e^2}{\kappa(q + q_s)}, \quad (21)$$

where q_s is given by

$$q_s = \frac{2\pi e^2}{\kappa} \int \left(-\frac{\partial f_0}{\partial \varepsilon} \right) D(\varepsilon) d\varepsilon. \quad (22)$$

This q dependence of $V(q)$ in Eq. (18) leads to the $n\varepsilon^{-1} \propto \varepsilon$ dependence of the momentum relaxation time. The relaxation time $\tau_m(\varepsilon_k)$ and the resulting conductivity calculated by integral of Eq. (15) becomes

$$\tau_m(\varepsilon) = \frac{n}{\pi g_s g_v n_i} \frac{\hbar}{|\varepsilon|} H \quad (23)$$

$$\sigma = \frac{e^2}{4\pi^2 \hbar} \frac{|n|}{n_i} H, \quad (24)$$

where H is the dimensionless constant determined by κ (Ando, 2006; Adam et al., 2007). This result accounts for the experimental observation $\sigma \propto n$. The mobility is independent of n and depends on the concentration of charged impurities:

$$\mu = \frac{e}{4\pi^2 \hbar} \frac{1}{n_i} H. \quad (25)$$

The mobility is experimentally evaluated from the carrier density or gate voltage dependence of the conductivity.

At the charge neutrality $n = 0$, the conductivity becomes minimum. The minimum conductivity is predicted to be

$$\sigma_{\min} = \frac{g_s g_v e^2}{2\pi^2 \hbar}, \quad (26)$$

for the short-range scattering irrespective of the value of the scattering probability W (Shon and Ando, 1998). However, in the presence of the long-range scattering, $\sigma_{\min}$ increases with W (Noro et al., 2010). Experimentally, $\sigma_{\min}$ differs sample by sample (Tan et al., 2007), which is consistent with the charged impurity scattering. Around $n = 0$, electron-hole puddles are locally present owing to inhomogeneity of graphene devices. Using the induced local carrier density n_p at the conductivity minimum, $\sigma \propto n$ is modified to $\sigma \sim \sigma_{\min} \sqrt{1 + \frac{n^2}{n_p^2}}$ around $n = 0$.

For bilayer graphene, the parabolic dispersion leads to $n \propto \varepsilon$ and $D(\varepsilon) \propto \varepsilon^0$. The form factor in Eq. (17) becomes $F(\mathbf{k}' - \mathbf{k}) = (1 + \cos 2\theta_{\mathbf{k},\mathbf{k}'})/2$, allowing large-angle scattering (no suppression at $\theta_{\mathbf{k},\mathbf{k}'} = \pi$). In a similar argument, we find $\sigma \propto n$ for the short-range scattering and $\sigma \propto n^2$ for the long-range scattering. Experimentally, $\sigma \propto n$ is observed in a wide range of n (Morozov et al., 2008). Therefore, it has been pointed out there is a scattering by a short-range disorder in addition to the screened charged impurities in bilayer graphene. $\sigma \propto n$ for both monolayer and bilayer graphene indicates that screening is much stronger in bilayer graphene than in monolayer graphene. Indeed, we find $q_s \propto n^{-1/2}$ in bilayer graphene (as in standard two-dimensional electron gas) while $q_s \propto n^0$ in monolayer graphene. The ratio of the screening constant between the bilayer and monolayer graphene $q_s^{\text{BLG}}/q_s^{\text{MLG}} \approx 16/\sqrt{n/10^{10}\text{cm}^{-2}}$ becomes significantly small (screening becomes significantly stronger in bilayer) as n increases (Das Sarma et al., 2011).

In the presence of a perpendicular electric field for bilayer graphene, the gap 2Δ opens (McCann, 2006, 2023; Oostinga et al., 2008). When the Fermi energy is tuned into the gap, the conductivity is suppressed. Such a gapped state can be prepared in a dual-gated device by tuning the carrier density n and the perpendicular electric field D independently. However, the conductivity in the gap is not so suppressed as in conventional semiconductors, where the conductivity is scaled to $\exp(-\Delta/k_B T)$ owing to the thermal activation across the gap. The low temperature transport in this regime is described by the variable range hopping through impurity-induced states. The conductivity is proportional to $\exp(-(T_0/T)^{1/3})$, where T_0 depends on the disorder in the device.

In general, the conductivity becomes approximately the sum of contributions from the variable range hopping and thermal activation across the gap: $G \approx G_1 \exp(-\Delta/k_B T) + G_2 \exp(-(T_0/T)^{1/3})$ (Miyazaki et al., 2010). The first term becomes more dominant for higher temperatures.

At high temperatures, carriers in graphene also suffer from scattering by phonons. Electrons are scattered by longitudinal acoustic (LA) phonons, optical phonons on the substrate, and ripples of graphene lattice. The resistivity ρ_{LA} induced by LA phonons (major contribution) is proportional to the temperature T , except at low temperature below Bloch-Grüneisen temperature $T_{BG} \approx 54 \sqrt{n(\times 10^{12} \text{ cm}^{-2})}$ K, where the phonon is degenerate and ρ_{LA} is suppressed as $\rho_{LA} \propto T^4$ (Stauber et al., 2007; Hwang and Das Sarma, 2008). Contributions of other phonons are nonlinear with T .

The contribution of phonon scattering in carrier transport is usually (in present devices) minor compared to the charge impurity scattering even close to the room temperature. For $T < T_{BG}$, intrinsic phonon-limited mobility is high and exceeds $10^6 \text{ cm}^2 \text{ V}^{-1} \text{ s}^{-1}$ (Hwang and Das Sarma, 2008).

Ballistic transport and electron optics

In typical clean graphene devices, the mean free path $l_m = \tau_m v_F$ is of the order of several microns when n is sufficiently large. This long mean free path allows for realization of ballistic transport by making the device dimension comparable with or smaller than l_m . Ballistic transport has already been observed and investigated in conventional semiconductors that have similar properties. However, unlike conventional two-dimensional electron gas systems, it is possible in graphene to tune the Fermi energy locally between the conduction and valence bands by means of local gates. This allows us to prepare in-plane p-n junctions in the ballistic regime. In this section, we discuss unique ballistic transport in bipolar graphene junctions. We focus on the Klein tunneling and electron optics in monolayer graphene. Unique properties in bipolar graphene devices originate from the pseudospin-momentum coupling as we have discussed.

It was predicted that a relativistic particle incident on an infinite potential barrier transforms into an anti-particle inside the barrier and moves freely in this otherwise forbidden region, resulting in perfect transmission through the barrier. This phenomenon is known as the Klein tunneling. In graphene, which has relativistic charge carriers, it is possible to demonstrate this Klein paradox on a chip (Katsnelson et al., 2006). We consider a normal incident charge carrier to a graphene n-p interface with a smooth potential which does not introduce inter-valley scattering by an atomic-scale short-range scattering. According to the pseudospin-momentum coupling in Eq. (1), the pseudospin of an incoming electron in the K point is parallel to the momentum. Since we assume the smooth n-p interface potential, the pseudospin is conserved in the tunneling process. Therefore, the electron impinging perpendicular onto the n-p junction cannot be backscattered into a counter propagating electron state which would be in the K' point. Instead, it is scattered into a hole state which has opposite momentum direction but with the same pseudospin as the impinging electron. This leads to the perfect transmission through the n-p junction.

In general, while normally incident particles perfectly transmit through the n-p interface, obliquely incident particles have a transmission probability which depends on the angle of incidence. There is also an analogy between the transmission of the carriers at the graphene n-p interface and optical refraction at the surface of metamaterials with negative refraction index. Using such refraction, incident particles can be focused by graphene n-p junctions. This is the principle of the electric current lenses in n-p-n or p-n-p structures, known as Veselago lenses in optics, in the ballistic transport regime (Cheianov et al., 2007).

The Klein tunneling has been demonstrated in dual-gated graphene p-n-p (n-p-n) junction devices. The junction is ballistic when the mean free path l_m is larger than the distance between the two n-p interfaces. The electrical resistance is larger in the ballistic transport regime than in the diffusive regime. This is because the tunneling probability for obliquely impinging electrons to each p-n junction is lower in the ballistic regime than in the diffusive regime due to the Klein tunneling process.

In a ballistic n-p-n or p-n-p graphene junction, quantum interference also occurs due to a resonant cavity between the two n-p interfaces (Shytov et al., 2008). The conductivity oscillates as a function of the carrier density of the cavity region. But this interference is suppressed for the normal incidence owing to the perfect transmission at both interfaces. The interference is dominated by modes at incident angles, where neither the transmission nor reflection probabilities are too large. The magnitude and phase of the transmission and reflection coefficients can be evaluated by this quantum interference in a perpendicular magnetic field B . The magnetic field B bends the trajectories of the carriers and modifies the incident angles of the carriers at the n-p interfaces. It also modifies the transmission and reflection coefficients at the interfaces. In a certain B range, contributions of zero transverse (y-direction) momentum modes become dominant, where the incident angles at the two interfaces have the same sign (see Fig. 2(b)). The trajectory of a particle in a round trip between the two interfaces encloses the origin $k_x = k_y = 0$ in the momentum space and the particle thus acquires the Berry phase π . This π phase shift is the hallmark of the Klein tunneling that should lead to the perfect transmission (zero reflection) in the normal incidence. The π phase shift of the conductivity oscillation was first observed by Young and Kim as shown in Fig. 2(d) (Young and Kim, 2009).

There are also other experimental works on electron optics in ballistic bipolar graphene junction devices. Chen et al. demonstrated Snell's law at the n-p interface by a magnetic focusing experiment (Chen et al., 2016). It was experimentally confirmed that refraction is negative at a n-p interface while it is positive at a n-n' or p-p' (the same polarity with different carrier densities) interface.

Fig. 2 Demonstration of the Klein tunneling in graphene. (a) schematic of interference in a n-p-n or p-n-p junction at $B = 0$. (b) schematic of interference for $B > 0$. (c) a color-coded plot of the derivative of the conductance with respect to the charge density induced by the top gate (n_2) as a function of top (n_2) and back (n_1) gate-induced charge densities. The top gated region is between the two n-p interfaces. The oscillations in conductance are apparent when the densities n_1 and n_2 have opposite signs. (d) Conductance G vs n_2 for fixed n_1 at different external magnetic field values applied perpendicular to the sample (from the bottom to the top conductance curve $B = 0, 200, 400, 600$ and 800 mT); the dots represent data, the smooth lines are the result of the simulations. The sudden phase shift of π that signals the presence of perfect transmission is indicated by dotted arrows. We find by tracing the arrows that the phase of oscillation changes by π between the green and purple curves. It corresponds to the change of the incident angle from the one depicted in (a) to that in (b). Curves are offset for clarity. Valley Hall transport in the presence of charged impurities

Berry curvature that we discussed in a previous section characterizes the intrinsic valley Hall effect. However, there are always extrinsic effects, i.e., influence of scatterers. It is more convenient to consider velocity operator to investigate influence of the scattering by charged impurities. Furthermore, discussion of the valley Hall effect in terms of the Berry curvature in Eq. (10) is semi-classical. Using the velocity operator and standard Kubo formula in the linear regime, we can investigate valley related quantum transport. The following argument was developed by Ando (2015a).

The velocity operator is defined as

$$\mathbf{v} = (v_x, v_y) = v_F \boldsymbol{\sigma} = v_F (\sigma_x, \sigma_y).$$

We consider massive monolayer graphene in Eq. (4). We perform a unitary transformation $U = \begin{pmatrix} 0 & 1 \\ -1 & 0 \end{pmatrix}$ on the Hamiltonian for K' valley ($\tau_z = -1$), which interchanges the sublattices. The Hamiltonian becomes

$$H = \hbar v_F (k_x \sigma_x + k_y \sigma_y) + \tau_z \Delta \sigma_z. \quad (27)$$

The equation of motion of the velocity operator becomes

$$\dot{\mathbf{v}} = \frac{1}{i\hbar} [\mathbf{v}, H] = 2v_F^2 (\mathbf{k} \times \boldsymbol{\sigma}) - 2\tau_z \frac{\Delta}{\hbar} \mathbf{v} \times \mathbf{e}_z \quad (28)$$

using the commutation relation of the Pauli matrices. The first term is the Zitterbewegung term. The second term corresponds to the anomalous Hall conductivity. It can be viewed as the Lorentz force due to the valley dependent effective magnetic field in the z -direction

$$\mathbf{B}_{\text{eff}} = \tau_z \left(\frac{\Delta}{\mu_B^*} \right) \mathbf{e}_z. \quad (29)$$

Here $\mu_B^* \equiv \hbar/2m^*$ is the effective Bohr magneton for the orbital magnetic moment of the valley. The role of the mass term is the valley Zeeman energy induced by the effective magnetic field in the real space.

The valley Hall conductivity for zero inter-valley scattering is calculated using the Kubo formula

$$\sigma_{xy}^K = \frac{4\hbar}{\pi i L^2} \int d\epsilon f(\epsilon) \left\langle \text{Tr} \left[\mathbf{j}_x \left(\frac{\partial}{\partial \epsilon} \text{Re } G(\epsilon + i0) \right) \mathbf{j}_y \text{Im } G(\epsilon + i0) - (x \leftrightarrow y) \right] \right\rangle, \quad (30)$$

where L^2 is the system size, $\mathbf{j} = -e\mathbf{v}$ is the current operator, $G(\epsilon) = (\epsilon - H)^{-1}$ is the Green's function, and $\langle \dots \rangle$ denotes average over configurations of scatterers. This also leads to Eq. (11). Note that the Berry curvature characterizes the response of the system to the shift in momentum space, while the effective magnetic field discussed here characterizes that to the charge diffusion. Similarly to that the drift charge current driven by the shift in momentum space and the diffusion current driven by the charge density gradient

are carried by the same conductivity, the Berry curvature and the effective magnetic field in Eq. (29) lead to the same Hall conductivity.

The work of Ando analyzes the influence of charged impurity scattering on the valley Hall effect. It is shown that even the slightest degree of scattering in the “clean limit” significantly modifies the valley Hall conductivity. The analytical result for zero temperature by the self-consistent Born approximation is given as

$$\sigma_{xy}^v(\varepsilon) = \begin{cases} \frac{2e^2}{h} \frac{8|\delta|(\Gamma_0 - \Gamma_1)[(1 + \delta^2)\Gamma_0 - 2\delta^2\Gamma_1 - (1 - \delta^2)\Gamma_2]}{[(1 + 3\delta^2)\Gamma_0 - 4\delta^2\Gamma_1 - (1 - \delta^2)\Gamma_2]^2} & (|\varepsilon| > \Delta) \\ \frac{2e^2}{h} & (|\varepsilon| < \Delta) \end{cases} \quad (31)$$

with $\delta = \Delta/\varepsilon$, and Γ_n are the broadening parameters that go to zero in the clean limit and are defined by the impurity density and potential profile. We find that the scattering does not modify $\sigma_{xy}^v(\varepsilon)$ in the band gap. Close to the gap but within the band continuum, we have

$$\sigma_{xy}^v(\varepsilon) \approx \frac{2e^2}{h} \frac{|\varepsilon|}{\Delta}. \quad (32)$$

Far away from the gap ($|\delta| \ll 1$), we have

$$\sigma_{xy}^v(\varepsilon) \approx \frac{2e^2}{h} \frac{\Delta}{|\varepsilon|} \frac{8(\Gamma_0 - \Gamma_1)}{\Gamma_0 - \Gamma_2}. \quad (33)$$

These show enhancement of $\sigma_{xy}^v(\varepsilon)$ in the band continuum. In particular, for the limit of short-range scattering, only Γ_0 remains nonzero. We therefore have

$$\sigma_{xy}^v(\varepsilon) \approx \frac{2e^2}{h} \frac{\Delta}{|\varepsilon|} \frac{8(1 + \delta^2)}{(1 + 3\delta^2)^2}, \quad (34)$$

showing 8 times enhancement of $\sigma_{xy}^v(\varepsilon)$ for $|\delta| \ll 1$ from that in Eq. (11). The results for different potential profiles are shown in Fig. 3. We see double-peak structure in $\sigma_{xy}^v(\varepsilon)$, plotted as a function of the energy, which persists unless the band gap is too small. In general, enhancement of $\sigma_{xy}^v(\varepsilon)$ in the band continuum is larger for the shorter-range scattering. This enhancement is also predicted for bilayer graphene (Ando, 2015b).

Enhancement of $\sigma_{xy}^v(\varepsilon)$ in the clean limit may be somewhat surprising. It already indicates that the intrinsic picture based on the Berry curvature cannot fully capture the valley Hall physics. It may have an analogy with the anomalous Hall effect driven by spin-orbit interaction. It is known there that the ultra-clean samples fall into the extrinsic regime, where the influence of external scatterers is dominant. The intrinsic regime is achieved in the moderately dirty regime. Similarly, the valley Hall effect in the clean limit is significantly affected by the profile of scatterers.

Fig. 3 Valley Hall conductivity and the density of states in the clean limit for scatters with Gaussian potential with varying potential range d . $\varepsilon_c \approx \hbar v_F$ is the cutoff energy. From Ando T (2015) Theory of valley hall conductivity in graphene with gap. *Journal of the Physical Society of Japan* 84: 114705.

Nonlocal transport and edge transport

The measurement of the nonlocal transport is widely used to detect the Hall conductivity. Once we have both the electrical conductivity σ_{xx} and valley Hall conductivity σ_{xy}^v , we can formulate the charge current and valley current in the presence of in-plane electric field semi-classically. The following conductance matrix form allows us to examine the conversion between the electric field E (in the x direction) and the electric current density j_c and that between E and the valley current density j_v (in the y direction) on a homogenous sheet:

$$\begin{pmatrix} j_c \\ j_v \end{pmatrix} = \begin{pmatrix} \sigma_{xx} - \sigma_{xy}^v \\ \sigma_{xy}^v \sigma_{xx} \end{pmatrix} \begin{pmatrix} E \\ E_v \end{pmatrix}, \quad (35)$$

where

$$E_v \equiv \frac{1}{2e} \frac{\partial}{\partial x} \delta\mu_v \quad (36)$$

is defined as the “valley field” induced by the chemical potential difference $\delta\mu_v = \mu_K - \mu_{K'}$ between the two valleys referred to as the “valley voltage.” Taking $E_v = 0$, the valley Hall effect is described by

$$j_v = \sigma_{xy}^v E. \quad (37)$$

as the conversion of the electric field into the valley current. Taking $j_c = 0$ and the inverse of the conductance matrix in Eq. (35), we find

$$E = \frac{\sigma_{xy}^v}{(\sigma_{xx})^2 + (\sigma_{xy}^v)^2} j_v. \quad (38)$$

This describes conversion of the valley current into the electric field.

The main source of valley relaxation is the scattering at armchair edges and atomic defects. To take into account inter-valley scattering, we employ a valley diffusion equation:

$$\frac{\partial^2}{\partial x^2} \delta\mu_v = \frac{1}{(l_v)^2} \delta\mu_v \quad (39)$$

This equation assumes homogeneous inter-valley scattering length l_v . Combining Eqs. (35) and (38) under an appropriate boundary condition, one can characterize the valley-related transport in a device.

Three groups have reported valley-mediated transport in a nonlocal measurement setup as shown in Fig. 4 (Yamamoto et al., 2015). Similar Hall bar devices have also been used for measurements of the spin Hall effect. In this setup, charge current I_c is injected into the left side of the device (between the contacts A and D), and voltage V induced in the right side of the device (between the contacts B and C) is measured. Nonlocal resistance is defined as $R_{NL} = V/I_c$. For $\sigma_{xy}^v \ll \sigma_{xx}$, the valley-mediated transport can be

Fig. 4 Hall bar geometry and nonlocal resistance measurement setup for generation and detection of the pure valley current. The charge current I_c between contacts A and D generates a pure valley current in its transverse direction via the valley Hall effect. This valley current is converted into a voltage between contacts B and C via the inverse valley Hall effect.

understood by a sequential conversion picture; the charge current I_c on the left is first converted into the transverse valley current with the conversion ratio given by the valley Hall angle $\alpha = \sigma_{xy}^v / \sigma_{xx}$ (valley Hall effect). This valley current is then converted back to the transverse charge current on the right with the conversion ratio again given by $\alpha = \sigma_{xy}^v / \sigma_{xx}$ (inverse valley Hall effect). This charge current is finally converted to the voltage V . Taking the conversion ratio of each process, we find that

$$R_{NL} \propto \alpha^2 \cdot \frac{1}{\sigma_{xx}} = \left(\frac{\sigma_{xy}^v}{\sigma_{xx}} \right)^2 \rho^3, \quad (40)$$

where $\rho = 1/\sigma_{xx}$ is the resistivity of the device. Using the horizontal width W of the Hall bar and the lateral distance L between contacts A and C, R_{NL} is given by

$$R_{NL} = \frac{W}{2l_v} \frac{\left(\sigma_{xy}^v \right)^2}{\left(\sigma_{xx} \right)^3} \exp \left(-\frac{L}{l_v} \right). \quad (41)$$

For $\sigma_{xy}^v \gg \sigma_{xx}$ on the other hand, we obtain

$$R_{NL} = \frac{W}{2l_v} \frac{1}{\sigma_{xx}} \exp \left(-\frac{L}{l_v} \right) \propto \left(\sigma_{xy}^v \right)^0 \rho^1. \quad (42)$$

The behaviors expressed by Eqs. (41) and (42) should be compared with the van der Pauw formula describing the contribution to R_{NL} of classical diffusive transport. Since graphene has high crystal quality, inter-valley scattering mainly occurs at the edges and therefore $l_v \sim W$.

The first experimental demonstration of the generation of pure valley current was reported for monolayer graphene aligned on hexagonal Boron Nitride (h-BN) crystal (Gorbachev et al., 2014). Since h-BN also has a hexagonal lattice with its lattice constant close to that of graphene, graphene aligned on h-BN is subjected to the periodic potential fluctuation of the boron and nitrogen atoms with its period observed as a moiré pattern. For appropriate angular alignment, this periodic potential produces mini-bands and associated band gap in the energy bands of graphene. Since the spatial inversion symmetry is broken owing to this periodic potential modulation, the valley Hall effect should occur. In the experiment performed by Gorbachev et al. (2014), such a high-quality monolayer graphene shaped into a Hall bar geometry aligned on single-crystal h-BN was employed to measure nonlocal resistance as discussed in the previous section.

Gorbachev et al. found that the nonlocal resistance R_{NL} is orders of magnitude larger than that estimated for the current diffusion. It was also confirmed that nonaligned graphene on h-BN, which is not subjected to the periodic potential modulation from the h-BN, does not show such a large R_{NL} . Observation of large R_{NL} was therefore attributed to valley-mediated transport. In addition, R_{NL} has a much sharper response to the gate voltage (which modulates the carrier density) than the resistivity ρ . It was interpreted as the consequence of nonlinearity of R_{NL} vs ρ in Eq. (40).

This experiment called forth debate concerning the microscopic picture of the nonlocal transport. In the experiment, the valley Hall effect was analyzed for metallic samples while the gap opening is supposed to be a necessary condition to confirm inversion symmetry breaking. It is now known that commensurate graphene/h-BN regions and incommensurate strained regions can form a domain-like structure (Woods et al., 2014) and thus the gap can be locally present even if the sample is metallic. Then the next question is whether the valley transport is mediated by the edge or bulk. Lensky et al. showed that bulk currents just beneath the gap may have dominant contribution to the valley current (Lensky et al., 2015). However, criticism was made that Eq. (40) is inapplicable for metallic samples because it is based on semi-classical theory. Indeed, theory by Ando indicates that the scattering by charged impurities should modify the theoretical curve of σ_{xy}^v used in the analysis. Based on the quantum transport model, completely different scenario for the experimental observation, where transport at the trivial edges make the dominant contribution to the observed R_{NL} , was suggested (Kirczenow, 2015; Marmolejo-Tejada et al., 2018). Recent observation of the non-topological edge current in charge-neutral graphene by a scanning SQUID (Aharon-Steinberg et al., 2021) also seems to support this scenario. Note, however, that existence of the trivial edge state was only observed at low (liquid helium) temperature and that the edge state is disordered.

Sui et al. (2015) and Shimazaki et al. (2015) employed a dual-gated structure, where a bilayer graphene flake is sandwiched by top and back gates through insulating h-BN layer. Independent control of n and D enabled them to investigate the valley Hall effect in the “insulating” regime.

Fig. 5 shows the gate voltage dependence of R_L and R_{NL} (data presented by Shimazaki et al., 2015). At the charge neutrality point (CNP), R_L is enhanced when D is increased due to the increase of band gap. R_{NL} also increases with D around the CNP. This is because σ_{xx} is reduced while σ_{xy}^v is enhanced with increasing D at the CNP. The measured R_{NL} is more than three orders of magnitude larger than the calculated ohmic contribution, excluding the ohmic contribution as the origin of the observed large R_{NL} .

Fig. 5(c) shows the scaling at the CNP for $T = 70$ K obtained by Shimazaki et al. (2015). At 70 K, the crossover between the band conduction (thermally activated transport across the band gap) and hopping conduction regimes occurs upon changing D . A cubic scaling (Eq. 40) is obtained in the band conduction regime of small D (green line) whereas saturation of R_{NL} is observed in the hopping conduction regime of large D by sweeping D at a fixed T . Sui et al. also observed similar nonlinear scaling between ρ and R_{NL} by sweeping T at a fixed D (Sui et al. 2015).

Since the device is highly resistive in this case, R_{NL} should be proportional to ρ if the edge transport is dominant. Sui et al. further excluded the edge contribution by employing a sample with a long edge (Sui et al., 2015). The nonlocal signal was comparable as

Fig. 5 Valley Hall effect demonstrated by the nonlocal transport measurement. A dual-gated bilayer graphene Hall bar device was employed, where bilayer graphene is sandwiched by the top gate and the back gate through h-BN flakes. (a) Gate voltage dependence of the local resistance R_L . It was measured as a function of the top gate voltage V_{TG} and the back gate voltage V_{BG} . The perpendicular electric field D is modulated along the red axis while the carrier density n is modulated along the green axis. The inset is a schematic description of the measurement configuration. The blue arrow stands for the charge flow. (b) Gate voltage dependence of the nonlocal resistance R_{NL} . (c) Scaling relation between the resistivity ρ and R_{NL} at the charge neutrality point (CNP). Each data point is extracted from the data in (a) and (b) for D ranging from 0.22–0.85 V/nm at the CNP. The inset shows the scaling relation in the band conduction regime observed with a different sample. Details are presented by Shimazaki et al. (2015).

long as the active sample length and width were the same, irrespective of the length of the sample edge. This result supports occurrence of the valley transport in the bulk.

The cubic scaling is the expected scaling for the intrinsic valley Hall effect (constant σ_{xy}^v) for $\sigma_{xy}^v \ll \sigma_{xx}$ near the CNP. For $\sigma_{xy}^v \gg \sigma_{xx}$, R_{NL} for the intrinsic regime is described by $R_{NL} \propto \rho$. The observed saturation of R_{NL} for large D and ρ may imply deviation from the intrinsic regime in the hopping conduction regime influenced by charged impurities. Microscopic picture of the observed valley-mediated transport is, however, not yet well understood.

Recently, similar nonlocal transport was reported for the charge neutral encapsulated bilayer graphene at $D = 0$ in the presence of a perpendicular magnetic field B , i.e., for the hall-filled 0th Landau level (Tanaka et al., 2021). Here, the electronic correlation leads to gap opening and the ground state becomes the interlayer antiferromagnetic state, where the spins align ferromagnetically in the in-plane direction within each layer but become opposite between the layers (Kharitonov, 2012). Such a state appears even at $B = 0$ for suspended bilayer graphene (Weitz et al., 2010), where the screening effect is weaker than encapsulated graphene. Each spin state is polarized in one of the layers, which is equivalent to the presence of a spin-dependent spontaneous perpendicular electric field that induces the spin-dependent valley Hall effect. This charge-neutral spin-dependent valley current mediates the nonlocal transport. It was shown that the large nonlocal transport in this state is observed even for a long-edge device and that it only appears when there is a quasi-long-range spin order in the bulk, i.e., below the Kosterlitz-Thouless transition temperature (Tanaka et al., 2022). This observation implies that this nonlocal transport is also mediated by the bulk region despite the criticism made for a different regime (Aharon-Steinberg et al., 2021).

Hydrodynamic transport

We have discussed carrier transport mostly in a single particle picture. However, at high temperatures where the electron-electron scattering time becomes shorter than that of scattering by charged impurities or phonons, carriers behave as fluids rather than independent particles or quasi-particles (Levitov and Falkovich, 2016).

Electron-electron scattering time in graphene is given by $\tau_{ee} \sim \hbar \varepsilon_F / (k_B T)^2$ in the degenerate case (far from the charge neutrality point). In a clean graphene device, the mean free path, or more precisely, the momentum relaxation length l_m can exceed the electron-electron scattering length $l_{ee} = v_F \tau_{ee}$ at high temperatures. The system then enters the “viscous” regime. Note that both the momentum relaxation time τ_m by the charged impurities and τ_{ee} are proportional to $\varepsilon_F \propto \sqrt{n}$. Therefore, l_m/l_{ee} has a weak dependence on n , and the viscous regime appears in a wide range of n . On the other hand, the temperature dependence is different between l_m and l_{ee} . While l_m decays slowly (slower than T^{-1}) with increasing temperature, l_{ee} decays quickly as T^{-2} . The viscous regime $l_{ee} < l_m$ appears at high temperatures typically above 100 K in a clean graphene device. Electron-phonon scattering length l_{e-p} induced by LA phonons is proportional to T^{-1} , decaying slower than l_{ee} for increasing temperature. Therefore, scattering by phonons does not become dominant over the electron-electron scattering and the viscous regime persists even close to the room temperature. This is in contrast with conventional semiconductors, where the viscous transport can be observed only at low temperatures ($< \sim 30$ K for HEMT).

The viscous flow can lead to local reversal of the current direction (Levitov and Falkovich, 2016; Bandurin et al., 2016). When an electric current is injected from a narrow constriction, current vortices appear near the constriction (see Fig. 6). The size of the vortices is characterized by $D_v = \sqrt{\nu \tau_m}$, which is determined by the viscosity $\nu \approx (1/2)v_F^2 \tau_{ee}$. Such a vortex induces a voltage drop at the position near the constriction, which is also interpreted as a hydrodynamic electron pump (Govorov and Heremans, 2004). D_v reaches submicron scale around the room temperature. Generally, electron transport for $l_{ee} \ll l_m$ is described by the following hydrodynamic equations:

$$\begin{aligned} \nabla \cdot \mathbf{j}(\mathbf{r}) &= 0 \\ \frac{\sigma_0}{e} \nabla \phi(\mathbf{r}) + D_v^2 \nabla^2 \mathbf{j}(\mathbf{r}) - \mathbf{j}(\mathbf{r}) &= 0, \end{aligned} \quad (43)$$

where $\mathbf{j}(\mathbf{r})$ is the current density, $\phi(\mathbf{r})$ is the electrostatic potential, and σ_0 is the Drude-like bare conductivity. The vorticity defined as

$$\boldsymbol{\omega}(\mathbf{r}) \equiv n^{-1} \nabla \times \mathbf{j}(\mathbf{r})$$

can be used to rewrite the hydrodynamic equation

$$\mathbf{j}(\mathbf{r}) = \frac{\sigma_0}{e} \nabla \phi(\mathbf{r}) - n D_v^2 \nabla \times \boldsymbol{\omega}(\mathbf{r}), \quad (44)$$

which leads to $\omega_z(\mathbf{r}) = D_v^{-2} \nabla^2 \omega_z(\mathbf{r})$, i.e., exponential decay of the vorticity over the length scale of D_v .

The hydrodynamic electron pump had been observed for a two-dimensional electron gas on a GaAs/AlGaAs heterostructure by injecting a current jet through a quantum point contact at low temperatures (Taubert et al., 2010). However, it appears more

Fig. 6 Current flow in the viscous (fluid transport) regime (a) and ohmic (particle transport) regime (b). White lines show current streamlines, colors show electrical potential, and arrows show the direction of current. Vorticities are generated for the viscous flow, which leads to the negative nonlocal voltage. From Levitov L and Falkovich G (2016) Electron viscosity, current vortices and negative nonlocal resistance in graphene. *Nature Physics* 12: 672–676.

robustly in graphene in a much wider range of the temperature. The voltage drop near the current jet is observed in the nonlocal transport when the distance L between the voltage probe contact and the current injection contact is less than or comparable with D_v . Bandurin et al. observed this voltage drop using a Hall bar device with $L = 1 \mu\text{m}$ for the temperature between $\sim 100 \text{ K}$ and $\sim 250 \text{ K}$ (Bandurin et al., 2016). The result agrees with the behavior expected from Eq. (43).

An even more remarkable phenomenon in the viscous regime is the “superballistic” flow (Guo et al., 2017) through a short constriction observed by Krishna Kumar and coworkers (Krishna Kumar et al., 2017). The conductance $G = G_{\text{sh}} + G_v$ in the viscous regime is enhanced from the Sharvin formula $G_{\text{sh}} = 4e^2 w \sqrt{\pi |n|} / (h\pi)$ for non-interacting electrons by $G_v = e^2 w^2 v_F \sqrt{\pi |n|} / (32\hbar v)$, if the width w of the constriction is larger than l_{ee} . This enhancement of the conductance is attributed to the additional contribution of slow-moving fluid near the edges of the constriction. The unusual w^2 scaling of the viscous conductance G_v was observed at high temperatures around 100 K (Krishna Kumar et al., 2017).

At the charge neutrality, carriers in clean graphene become the electron-hole plasma known as the Dirac fluid (Müller and Sachdev, 2008; Müller et al., 2009; Crossno et al., 2016; Gallagher et al., 2019). The Dirac fluid of graphene serves as the experimental model for high energy physics such as the black hole and quark-gluon plasma. The particle scattering time is given by $\tau_{ee} \sim \hbar / (k_B T)$, known as the Planckian time, the shortest possible timescale for particles to relax. Note that the Planck time in the Planck units is defined as $t_p = \sqrt{\hbar G / c^5}$ using the gravitational constant G and the speed of light c . Using the Planck temperature $T_p = \sqrt{\hbar c^5 / (G k_B^2)}$, the Planck time can be rewritten as $t_p = \hbar / (k_B T_p)$.

The residual carrier density at the charge neutral point should be made smaller than the density of thermally excited carriers to realize the Dirac fluid. The viscous flow of the graphene Dirac fluid was observed recently by imaging the current flow through graphene channels using the scanning quantum spin magnetometer of nitrogen vacancy centers in diamond at room temperature (Ku et al., 2020). When the width w of the channel is smaller than l_m , the current density concentrates more around the center of the channel than close to the edges. From its profile, it was confirmed that the scattering rate is close to that of the ideal Planckian limit.

Conclusion

Fundamental transport properties of graphene have been revealed both experimentally and theoretically. High-mobility graphene devices exhibit unique ballistic transport while the main source of carrier scattering in graphene is charged impurities at low temperatures. At high temperatures, electron-electron scattering becomes significant in clean graphene devices, and carriers behave as fluids. Topological valley transport also occurs in graphene when the inversion symmetry is broken. All these properties have been experimentally confirmed. Based on the obtained fundamental transport properties, novel functional devices are being developed. Graphene can also be used in combination with other materials in van der Waals heterostructures.

While most of the properties are now understood, there are still some ongoing controversies. These include topological transport in the gapped states in the presence of disorder. Recent experimental and theoretical works have pointed out contribution of unwanted edge transport in the nonlocal transport experiment. Further study should address microscopic picture of the topological transport in future.

Abstract

van der Waals (vdW) materials are composed of weakly bonded two-dimensional (2D) layers that can be easily isolated and re-stacked into heterostructures composed of different 2D materials. The vdW heterostructures add an increased range of functionalities to the variety of existing 2D materials, owing to the large variety of heterostructures that can be engineered. The properties of heterostructures can be further tuned by controlling the twist angle, the stacking order, or the contents of the interlayer spacing, among other things. All these make of the vdW heterostructures potential candidates for a plethora of applications for novel electronic and optoelectronic devices.

Key points

- van der Waals heterostructures are made of weakly-bonded 2D layers.
- Heterostructures can be assembled layer by layer.
- The weak interlayer interaction and the absence of dangling bonds allow a high flexibility for the stacks, without the usual restrictions for non-layered materials.
- But albeit weak, the interaction between adjacent layers can have a strong impact in their atomic structures and band structures.
- Overall, the physical properties of the heterostructures arise from the interaction between the different layers, giving rise to more complex behaviors than in isolated 2D materials.
- Among the different parameters that control the properties of the heterostructures are the relative orientation of the layers, their specific sequence and thickness, and the interlayer distance.
- The well-defined interlayer space can also be used to control the properties of the heterostructures by the intercalation of different species.
- The emergence of unconventional superconductivity and strong electron correlations, topological conducting channels, and moiré interlayer excitons are a few of the interesting phenomena observed in heterostructures so far.

Introduction

van der Waals (vdW) materials are composed of stacked atomically thin layers bonded together by weak vdW interactions, but with strong covalent bonding within each layer. The weak bonding between adjacent layers allows to isolate individual layers, having thicknesses that range from single- to a few-atoms depending on the specific material. The quantum confinement due to the decreased thickness in these layers has a profound impact on their electronic, optical, and magnetic properties, which can largely differ from that of their bulk counterpart and are hence considered as two-dimensional (2D) materials. In 2004 graphene was

obtained from graphite, becoming the first 2D material isolated from its corresponding bulk crystal and leading to the development of the 2D materials research field (Novoselov et al., 2004). Since then, the increased interest in these ultimately thin materials has allowed to continuously expand the library of available 2D vdW materials. The 2D materials discovered so far encompass a broad range of optical and electronic properties, making them interesting candidates for several applications.

The nature of the vdW forces and the absence of dangling bonds in the surface of the 2D materials allow to stack layers of different materials into heterostructures, without the constraints existing for non-layered materials (Koma, 1992). It is thus possible to produce heterostacks with arbitrary kinds of layers and with any relative orientations between them. Ultimately, the properties of the heterostructures depend on both the specific layers that compose them, as well as on their relative orientation and on the interlayer distance. This provides unprecedented ways to finely tune the properties of the heterostructures that are not available for bulk materials. It was thus soon realized that the range of options provided by the 2D materials could be vastly expanded by their combination into different kinds of vdW heterostructures. But although weakly bonded, the adjacent layers conforming the heterostructure can strongly affect each other, experiencing structural changes and modifications in their band structures that must be considered and that originate many of the observed properties.

The first examples of vdW heterostructures involved the use of hexagonal boron nitride (hBN), with a structure similar to that of graphene, as a high-quality dielectric to improve the performance of graphene devices (Dean et al., 2010; Haigh et al., 2012). The amount of heterostructures studied since then has grown remarkably, including layers of 2D materials as graphene, hBN, different transition metal dichalcogenides (TMD), among others, and spanning a wide variety of mechanical, electrical, optical and chemical properties. The assembly methods have continuously improved, allowing to produce high quality heterostructures with virtually clean interlayer spaces. All these has led to the discovery of novel and unexpected phenomena, such as the superconductivity in certain heterostructures, along with the realization of functional devices that exploit the advantages of the vdW heterostructures. But despite all the progress, improvements in the fabrication and handling of heterostructures toward industrial scalability are still required.

Overview

van der Waals layered materials and their heterostructures

The vdW layered materials are composed by stacks of planar crystalline layers. Each of the layers is composed of covalently bonded atoms in the in-plane direction, while their surface is free of dangling bonds. Hence, the stacked layers are held together to each other only by the weak vdW interactions between adjacent layers. This structure of weak bonded layers makes vdW materials different from other 3D materials, and allows for the easy exfoliation of individual layers without causing them any structural damage. These isolated layers, known as 2D materials, are crystalline structures with either single- (e.g., in the case of graphene), or few-atom thickness (e.g., any TMD or bismuth strontium calcium copper oxide (BSCCO)). The currently existing 2D materials encompass the whole range of electronic properties, from superconductors (e.g., NbSe₂, BSCCO), metals (e.g., borophene, VS₂), semimetals (e.g., graphene, 1T-TiSe₂), half metals (e.g., 1T-CrO₂), semiconductors with different sized gaps and band alignments (e.g., MoS₂, WS₂, InSe, black phosphorus), topological insulators (e.g., Bi₂Te₃) and insulators (e.g., hBN), ferromagnetic and antiferromagnetic 2D materials (e.g., CrI₃, FePS₃), and ferroelectric (e.g., SnSe). The most famous member of the 2D family is graphene, consisting of a honeycomb of sp²-bonded C atoms. Graphene is a semimetallic material, with conical valence and conduction bands for low energies that cross at the corners of the Brillouin zone (Dirac points). The linear dependence between the energy and the momentum results in the charge being carried by massless Dirac quasiparticles, described by the relativistic Dirac equation and moving at the Fermi velocity in graphene ($\sim 10^6$ m/s). This results in graphene having exceptional electronic properties, including the highest mobilities reported so far for any known material.

High quality flakes of the different 2D materials can be easily obtained by mechanical exfoliation from their corresponding bulk crystal, which in general produces flakes with very high qualities. However, this is a low yield method that only provides flakes with limited lateral sizes. Synthesis for the direct growth of 2D materials, such as by chemical vapor deposition (CVD), molecular beam epitaxy (MBE) or vapor-phase epitaxy based methods, are being continuously developed and improved (Cai et al., 2018). The advances realized in the growth of vdW materials have made possible the obtention of several of the known 2D materials at wafer-scale sizes, and with qualities that in certain cases can match those of their mechanically exfoliated counterparts. The methods for the growth of graphene and of some transition dichalcogenides (TMD) are specially developed, allowing to synthesize them with a good control of the quality and uniformity. Existing methods can in certain cases also provide some control in the thickness of the 2D materials, ranging from single to few layers, although the uniformity usually decreases for crystals thicker than one layer. But despite the considerable advances mentioned, improvements in the synthesis and the processing of 2D materials are still necessary to meet the requirements for large-scale practical implementations.

The absence of dangling bonds in the surface of the 2D materials, together with the universality of the vdW forces, ensures the opportunity to stack layers of 2D materials into heterostructures without the usual restrictions for other materials. It is thus possible to stack layers of completely different vdW materials without restrictions in their structure, lattice constant or relative orientation, and with well-defined interfaces (Koma, 1992; Liu et al., 2021). This, along with the variety of existing 2D materials, provides a great flexibility to realize vdW heterostructures with completely different characteristics and properties. When layers are assembled into heterostructures, the coupling between them induces complex interlayer interactions, enhancing the hopping of carriers and the charge redistribution between layers, and causing lattice reconstructions. Hence, the properties of the heterostructure cannot be

explained by a simple superposition of the properties of each layer. As will be seen below, the properties of the heterostructures depend on the specific sequence of the stacked layers, their thickness, and their relative orientation.

To highlight the large impact that stacking of 2D materials can have in their properties, the special case of vdW heterostructures comprised of layers from the same material can be considered. In the case of bilayer graphene (BLG), the band structure differs from that of the single layer graphene (SLG). The energy dispersion of AB-stacked BLG is parabolic, with the charge carriers being massive Dirac fermions, and the possibility to open a bandgap by applying a vertical electrical field. And as will be shown below the band structure of BLG is very sensitive to the twist angle between the layers, with the most spectacular effect being the emergence of unconventional superconductivity for low twist angles. It is also worth mentioning the case of stacks of black phosphorus (phosphorene) layers. Phosphorene is a semiconducting allotrope of P with a direct bandgap that decreases with the thickness, from ~ 1.5 eV for one layer to ~ 0.3 eV for bulk black phosphorous. This tunable bandgap and the relatively large mobilities that possess (~ 1000 $\text{cm}^2\text{V}^{-1}\text{s}^{-1}$) make of phosphorene an interesting material with properties bridging those of graphene and TMDs. However, phosphorene is easily degraded by oxygen, water, and light, thus requiring handling in controlled environments, and a proper encapsulation and/or surface passivation of the final devices.

Assembly and growth of vdW heterostructures

The most extended way to fabricate vdW heterostructures consist in assembling them by stacking thin flakes exfoliated from bulk materials (Frisenda et al., 2018). The technique has improved through the years, with the current preferred methods relying on the vdW layer-by-layer pick up (Fig. 1). In these, a 2D flake (generally hBN) is mounted on a polypropylene carbonate (PPC)/polymeric stamp and then used to assemble the heterostructure by the successive pick-up of flakes that were previously exfoliated onto SiO_2 substrates. The strong adhesion between the layers of the different vdW materials is key here for the success of the transfer. The main advantage of this layer-by-layer pick up is that the trapped interlayer contamination is significantly reduced, as the layers of the heterostructure are never in direct contact with any polymer during the whole assembly process. Another benefit is the possibility to perform the assembly in an inert ambient in order to produce heterostacks of air-sensitive 2D materials, such as phosphorene, encapsulated by hBN that eventually protect them from damage from air exposure. The *layer-by-layer* assembly methods also provide a way to produce heterostacks with controlled relative twisting of adjacent layers, provided that the orientation of each flake has been previously determined. Control of the twist is especially precise in the assembly variant known as *tear-and-stack* (Fig. 2), in which a part of a single crystal flake is picked by the hBN/stamp (*tear*), rotated the desired angle, and then transferred onto the rest of the flake (*stack*) (Kim et al., 2016). This method allows to assemble vdW stacks with sub-degree accuracies in the twist angle and without the need to determine the crystal orientation of the original flake.

The downside of the existing assembly methods is the low yield and the limitation to small areas, which is unsuitable for large-scale processing. The obtention of 2D crystals by mechanical exfoliation results in very sparse flakes located at random positions and of small areas, making the task to identify and process them into heterostructures extremely difficult. To improve this, progress is being made in automating the assembly with the aid of robotic systems (Masubuchi et al., 2018). These systems can autonomously find exfoliated flakes with the required thickness and assemble them into the specified heterostructures. The use of such systems substantially increases the assembly speeds compared to manual methods. But although suitable for small-scale research studies, the problem of the small size of the exfoliated flakes persists. To achieve the large-scale assembly of vdW

Fig. 1 Schematics of the vdW *layer-by-layer pick up* technique to fabricate heterostructures. An hBN mounted in a PPC/polymer stamp (i) is used to pick up a flake previously exfoliated on a SiO_2 substrate (ii). The process can be repeated, and eventually the heterostructure is brought to contact with the target substrate (iii, iv) and the stamp is removed, leaving the heterostructure on the new substrate (v).

Fig. 2 Schematics of the *tear-and-stack* technique to fabricate heterostructures with controlled twist angles. In this case, the hBN only picks part of the flake (i, ii), while the rest remains on the substrate. The hBN is then rotated to the desired twist angle (iii), and brought to contact with the remaining part of the flake (iv, v).

heterostructures, alternatives to the mechanically exfoliation are required. As mentioned in the previous section, scalable methods to produce and process most of 2D materials are being continuously developed. This is crucial for the practical implementation of heterostructures at industrial-scale processes. Other than the availability of large areas, the use of bottom-up synthesized 2D materials possesses other advantages, such as the possibility to control the crystal orientation during the growth (e.g., for CVD and MBE growths on certain substrates). On the other hand, the crystal quality does not always match that achieved by mechanical exfoliation yet. Also, the assembly techniques for large areas are still not as developed as those for small crystals, although methods specialized in wafer-scale sizes and rigid substrates are being actively developed (Quellmalz et al., 2021).

The next step to improve the scalability is the direct growth of the vdW heterostructures, which can avoid the difficulties arising during the assembly by artificial stacking. The epitaxial growth of heterostructures of van der Waals layered materials, with thickness down to a single layer, was already reported in pioneering works in the last decades of the past century (Koma et al., 1984; Ueno et al., 1990; Koma, 1992). The direct growth methods can also potentially result in cleaner layer interfaces by avoiding the trapped contamination originated during the assembly. However, the progress here is not as developed as for the growth of 2D materials, as processes involved in the direct synthesis of heterostructures are usually more complex. This is caused in part by the different growth conditions required for each of the different materials conforming the heterostructure. These different growth conditions and the instability of some 2D materials can also result in damage of one of the materials during the synthesis of the rest. Moreover, the uniformity of the heterostructures that have been grown so far are usually low and limited to small sizes. The control of the stacking angle is also more difficult when directly growing heterostructures. Whereas the assembly methods easily allow to produce heterostructures with arbitrary stacking orders, the relative orientation of the layers in direct growths tends to correspond to the most stable stackings. Thus, as-grown TMD/TMD heterostructures commonly form 0° and 60° twist angles, for BLG the most stable configurations are 0° (or AB) and 30° , while graphene/hBN heterostructures tend to be aligned. But although still limited, methods already exist for the direct growth of vdW heterostructures. The most paradigmatic case is the growth of TMD heterostructures in which the layers differ only by a chemical element, i.e., when they share the same chalcogen ($MX_2/M'X_2$) or the same metal (MX_2/MX'_2). The vapor phase growth of such TMD heterostructures, e.g. of WS_2/MoS_2 , is made possible by carefully selecting the precursors and the temperatures (Gong et al., 2014). Transition metal oxides (TMO), such as WO_3 or MoO_3 , are commonly used as precursors for the vapor phase growth of TMDs. This enables the growth of TMO/TMD heterostacks by controlling the synthesis process (Zheng et al., 2019). The growth of heterostructures can sometimes involve two-step approaches in which one of the layers is grown first. This first layer usually serves as a template for the growth of the next layers, by either slightly adjusting the growth conditions (e.g., the precursors or the temperature reaction) or by a completely different growth procedure (Solís-Fernández et al., 2017). Among the most used template layers are graphene and hBN, for which the growth of several heterostructures have been documented, such as hBN/graphene (or graphene/hBN) and of hBN or graphene with different TMDs. The template layer can also be engineered to promote the growth of the subsequent layers, for example by the controlled introduction of defects. Other than to facilitate the growth of the heterostructure, this also provides a way to selectively nucleate the second layer at the desired positions and obtain arbitrary arrangements (Li et al., 2020). Finally, it is worth mentioning that besides from the vertical heterostructures covered here, there are also direct growth methods for growing in-plane heterostructures with 1D interfaces (Solís-Fernández et al., 2017). This kind of heterostructures, which are interesting to produce in-plane devices, cannot be accomplished by artificial assembly methods.

Clean interlayer interfaces

One important factor in the fabrication of high-quality vdW heterostructures is the obtention of well-defined and free of contamination interfaces between adjacent layers. As an example, the mobility of hBN/SLG/hBN devices can increase up to an order of magnitude when the interfaces between the layers are clean. As previously mentioned, the *layer-by-layer pick up* assembly

Fig. 3 (A–C) AFM images of graphene on hBN (A), MoS₂ (B) and WS₂ (C), showing the presence of bubbles and wrinkles resulting from the aggregation of the interlayer contamination due to the self-cleaning mechanism. (D) Cross-sectional TEM image of a graphene/hBN heterostacks along one of the contamination bubbles. (E–H) Mechanically pushing the contamination bubbles in a hBN/graphene/hBN heterostacks during the transfer to produce cleaner interfaces. (I) Cross-sectional STEM image and the corresponding schematics of a clean SLG/hBN/SLG/hBN heterostructure. The graphene layers are evidenced in the averaged intensity profile along the dashed line. The lack of contamination is evidenced by the interlayer spacing between the SLG and hBN regions being indistinguishable from the interlayer distance of bulk hBN within the experimental accuracy. methods significantly decrease the amount of contamination as compared with other transfer techniques, even when the assembly is performed in air at ambient conditions. Interestingly, the atomically flat surface of the layers and their mutual interactions produces a *self-cleansing* of the interface (Haigh et al., 2012; Kretinin et al., 2014; Novoselov et al., 2016). The contaminants existing in the interlayer space, mainly composed of hydrocarbons, water and air, aggregate into bubbles due to the larger inter-layer affinity as compared with that of the layer-contaminant (Fig. 3A–D). The cleansing mechanism ensures that most of the interlayer area remains clean, allowing to obtain interlayer distances of the artificial stacks almost indistinguishable from those observed in natural crystals. Additional cleaning can be achieved by annealing the heterostructure, which increases the mobility of the contamination bubbles and allows them to further aggregate into larger ones or to escape from the edge of the heterostructure. Heating is especially effective during the last step of the *layer-by-layer* assembly when the assembled heterostack/stamp is brought into contact with the target substrate. The increased bubble mobility at high temperatures can be combined with a mechanical pushing of the bubbles, as seen in Fig. 3E–H, in which the bubbles in the heterostack (Fig. 3E) are being pushed away as the sample is carefully brought into contact with the substrate (Fig. 3F and G), leaving a nearly clean interface in most of the heterostack (Fig. 3H) (Purdie et al., 2018). The contamination bubbles can thus be pushed out of the active areas of devices during the transfer procedure, leading to virtually clean device stacks (Fig. 3I).

Moiré patterns and twistronics

The possibility to stack layers of 2D materials with arbitrary twist angles provides an additional degree of freedom to tune the band structure of the vdW heterostructures. A moiré pattern with a periodicity larger than the original lattice constants is formed when there is a lattice mismatch and/or a misalignment between adjacent layers in a vdW heterostructure. In most cases, the wavelength of the moiré superlattice can be expressed as

$$\lambda = (1 + \delta)a / \sqrt{2(1 + \delta)(1 - \cos \theta) + \delta^2} \quad (1)$$

for a twist angle θ and a lattice mismatch $\delta = a/b - 1$, where a, b are the lattice constants of the crystal layers. The expression can be approximated as $\lambda \approx a / \sqrt{\theta^2 + \delta^2}$ for crystals with similar lattice constants ($\delta \ll 1$) and small twist angles, evidencing that long period superlattices are formed for small twist angles and crystals with similar lattice constants. For the case of no lattice mismatch (e.g., when stacking layers of the same material), the expression simplifies to $\lambda = a / \sqrt{2(1 - \cos \theta)}$ ($\approx a / \theta^2$ for small twist angles). Fig. 4 shows scanning tunneling microscope (STM) and scanning transmission electron microscope (STEM) images of moiré patterns on twisted bilayer graphene (TBG) with different twist angles, evidencing the wavelength decrease with the twist angle (Lin et al., 2021b). The orientation of the moiré superlattice relative to the crystal lattices (ϕ) is given by $\tan \phi = -\sin \theta / ((1 + \delta) - \cos \theta)$.

The physical properties of vdW heterostructures are strongly dependent on the moiré superlattice. The interlayer separation and the band structure vary with the moiré superlattice. This allows to modify the optical and electrical properties of the heterostructure in novel ways, giving rise to a nascent research field known as twistrionics. The occurrence of the moiré pattern causes a modulation of the interlayer coupling that results in a superlattice potential. This eventually induces the emergence of different properties in vdW heterostacks, including ferromagnetism, the occurrence of topological conducting channels, moiré excitons, and of unconventional superconductivity and strong electron correlations. Given their importance, the cases of low angle TBG and of twisted graphene/hBN heterostructures will be described in subsequent sections. The effects of the twist in interlayer excitons will also be explored in the section devoted to TMD heterostructures.

Superlubricity and self-rotation of layers

As discussed in the previous section, one of the factors defining the properties of vdW heterostructures is the relative orientation of the adjacent layers, or the twist angle. It is thus of paramount importance to control the twist angles with a great accuracy when assembling the heterostructures. However, the nature of vdW interlayer interactions resulting in clean interfaces and weakly bonded layers, allows the layers to both slide and self-rotate up to some extent when displaced from their equilibrium configuration, in order to attain a favorable stacking that minimizes the interlayer vdW energy.

States of ultra-low friction have been measured and predicted between layers of graphite, in a phenomenon coined as superlubricity Dienwiebel et al. (2004). In general, superlubricity can happen when two weakly bonded crystal surfaces are stacked in an

incommensurate state, either due to a relative rotation or to a displacement. This low friction allows for easy rotations and/or sliding between commensurate states (Fig. 5A–C). Such low friction regimes have for example been observed in the case of TBG stacks, of graphene/h-BN heterostacks, and of heterostacks of a TMD and graphene or h-BN. In the case of graphene/h-BN, rotations of over 10° and for crystals with sizes of up to few tens of microns can be observed upon annealing at temperatures over 100°C , tending to produce the most stable stackings of 0° and 30° (Fig. 5A–C) (Wang et al., 2016; Woods et al., 2016). All this must be accounted when stacking layers, and attention must be paid to achieve the required twist angles. As an example, producing TBG with low stacking angles (which will be covered later) requires working at low temperatures and assembling the stack with a slightly larger angle than the final target angle. This is done to account for some relaxation to the preferred Bernal stacking even at room temperature. But although detrimental in most cases, the low friction between layers can be exploited to construct rotatable vdW heterostructures in which the characteristics can be finely tuned at demand by precise rotations (Fig. 5D–H) (Ribeiro-Palau et al., 2018).

Atomic reconstruction

Other than by self-rotation, the interlayer energy in vdW heterostructures can decrease by local atomic rearrangements. Atomic reconstruction in adjacent layers of vdW heterostructures can happen when either the layers have similar lattice constants, or when the twist angle is low for two similar layers. The moiré superlattice gradually varies across the surface in the absence of reconstruction (Fig. 6A). Although the vdW interactions between the layers are usually considered to be weak (generally a few meV per atom), they cannot be neglected for small twist angles. When the interlayer coupling is strong enough, the atoms of each layer can relocate to a new configuration that equilibrates the inter and intralayer forces (Fig. 6B), thus minimizing the stacking potential energy. This results in a commensurate-incommensurate transition and the formation of commensurate regions, either by small local shifts of the layers or by strain to adjust the different periodicities of the lattices. The commensurate regions are limited by sharp soliton boundaries that concentrate most of the deformation. Reconstructions have been experimentally observed in several kinds of heterostructures, including TBG, graphene/hBN, or in different TMDs heterostructures. The process of the reconstruction can be exemplified by the case of TBG represented in Fig. 6C–F (Carr et al., 2018; Yoo et al., 2019). For small twist angles a series of triangles can be seen in images from different experimental techniques (e.g., TEM and AFM), corresponding to alternating domains of almost perfect AB- and BA-stacking limited by sharp soliton boundaries. The contrast between the regions decreases as the twist angle increases, and for angles larger than $\sim 1^\circ$ the lattice commences to appear like a non-reconstructed rigid moiré

Fig. 6 (A, B) Schematic of TBG before (A) and after (B) the atomic reconstruction. (C–F) Dark-field TEM images of TBG with different twist angles. The triangles seen at lower angles correspond to the reconstructed AB and BA areas. The contrast between those regions weakens as the angle increases, and eventually linear fringes emerge, commonly observed in the absence of reconstruction. (g) Real space map of the calculated interlayer energy per unit cell of relaxed TBG for different incommensurate twist angles (the size of each area is $40 \times 40 \text{ nm}^2$). superlattice. The transition from the relaxed to the rigid regime when increasing the twist angle has been observed for other heterostructures, although the critical angles vary depending on the specific material. Such trend in the relaxation has also been described by theoretical models (Fig. 6G). Stacks of other 2D materials can result in more complex atomic reconstructions, as exemplified by the case of TMD heterostacks, such as the WSe₂/MoSe₂ shown in Fig. 7 (Rosenberger et al., 2020). In this case, for twist angles close to 0° the reconstruction includes AB and BA triangular domains similar to those occurring in TBG. However, the symmetry of the TMDs results in a reconstruction into hexagonal shaped domains of a single arrangement (ABBA) for twist angles close to 60°.

Twisted bilayer graphene and superconductivity

One of the most paradigmatic and studied cases of the moiré influence on the band structure is that of the emergence of *unconventional* superconductivity in low-angle TBG. The occurrence of large AA- and AB-stacked regions for such low angles introduces small variations of the interlayer distance for the different regions, which result in fluctuations of the interlayer coupling

Fig. 8 (A) Calculated normalized local density of states of the flat bands with $E > 0$ of TBG with a twist angle of 1.08° . The wavefunctions are concentrated on the AA regions, having a much smaller amplitude in the AB and BA regions. (B) Band energy in the first mini-Brillouin zone of the superlattice of TBG with a twist angle of 1.05° , and the corresponding density of states with the Fermi energy located at the half-filled state of the flat band with $E < 0$ in which the superconductivity is observed. For comparison, the density of states of two layers of single-layer graphene without interlayer interaction is also included. (C) Four-probe resistance curves of TBG devices with twist angles of 1.05° and 1.16° (an optical image of the latter is shown in the inset), with critical temperatures of 1.7 K and 0.5 K, respectively. Each measurement is performed for the Fermi energy near the half-filled state of the $E < 0$ energy flat band. (D) Four-probe resistance plotted as a function of the carrier density and temperatures for a TBG device with a twist angle of 1.05° and a critical temperature of up to 1.7 K. The two superconductive domes (in blue) near the half-filled state are located at a carrier density of around $n \approx -1.3 \times 10^{12} \text{ cm}^{-2}$. (E) Temperature dependence of the four-probe resistance curves of a TBG device with a twist angle of 1.27° at different applied pressures. The high-pressure measurements in (E) were done at the optimal doping of the superconductor. (A) Reproduced with permission Cao Y, Fatemi, V, Demir A et al. strength. These fluctuations were used to predict the vanishing of the Fermi velocity in TBG and the occurrence of flat bands near the charge neutrality for certain low twist angles, known as *magic angles*, with the first one occurring at $\sim 1.1^\circ$ (Cao et al., 2018b; Andrei and MacDonald, 2020). The flat bands are mainly localized in the AA-stacked regions, as evidenced in Fig. 8A, and correspond to levels with energies that are mostly independent of the electron momentum (Cao et al., 2018a). The flat band energy and the corresponding density of states are depicted in Fig. 8B. Interaction between the electrons increases for twists near the *magic angles*, and a strongly correlated system is formed with Mott-like insulating states at half-filling of the flat bands, i.e., for two charge carriers per moiré unit cell. However, the complete implications of these strong correlations were not clear until experimental results could be obtained a few years later, in 2018. The low carrier densities at which the flat bands occur, slightly over 10^{12} cm^{-2} , are easily attained by electrostatic doping in conventional gated devices. The main difficulty arises from the complexity to fabricate the devices with the exact required twist angles, while avoiding the tendency of the TBG to relax to AB-stacking. The experimental results revealed the emergence of *unconventional* superconductive states for TBG with a twist angle of $\sim 1.1^\circ$ (Fig. 8C) (Cao et al., 2018b). The term *unconventional* refers to the fact that these states are not originated by the weak electron-phonon interactions of conventional superconductors, but are instead supposed to arise from the aforementioned strong correlations between electrons in the flat bands. The *magic angle* TBG have a low critical temperature (T_C) of up to ~ 1.7 K that depends on the twist angle. Although this T_C is low for any practical application, the simplicity of TBG is expected to help understanding the mechanism underlying unconventional superconductivity and lead to the development of superconductors with higher T_C . The superconductive states were originally observed near the correlated-insulating states at half-filling of the flat bands of the valence band ($E_F < 0$), displayed as the two low-resistance domes at both sides of the insulating states in Fig. 8D. Conversely, no superconductivity was observed near the flat bands of the conduction band. Since then, superconductive states have been found at lower temperatures in a wider range of fillings in both the conduction and valence bands (Lu et al., 2019). It is also worth mentioning the emergence of ferromagnetic states near three-quarters filling of the conduction band, for which the magnetization can be controlled by applying a small current (Sharpe et al., 2019).

Superconductivity can also be induced in TBG with angles larger than the *magic angle* and at higher critical temperatures by tuning the interlayer distance, for example by the application pressure (Fig. 8E) (Yankowitz et al., 2019a). This highlights the importance of the interlayer coupling in the properties of the heterostructures and provides an additional parameter to tune the properties of vdW heterostructures.

Other than for TBG, the emergence of correlated insulated states and of superconductivity has also been predicted in other twisted bilayer vdW heterostructures, including bilayers of hBN and of TMDs, and for some trilayer or thicker heterostructures. The most recent experimental results show signatures of superconductivity in certain heterostructures, such as in twisted trilayer graphene (TLG) superlattices, in superlattices between ABC-stacked TLG and hBN, and in twisted WSe₂. However, the complexity of experimentally realizing such heterostructures is slowing down the confirmation of predictions.

Graphene/hBN heterostructures

The case of graphene/hBN heterostructures will be described here in some detail, as it is one of the most studied vdW heterostructures given its technological importance. For a more exhaustive review on the topic, the reader is referred to Yankowitz et al. (2019b). The 2D materials are very susceptible to their immediate environment, given that most of their atoms are in their surface. Hence, some 2D materials can be unstable and damaged when exposed to oxygen, moisture or to light. The environment can also significantly alter the properties of stable 2D materials, as can be seen in the p-doping of graphene exposed to air. It is thus important to properly isolate them by selecting adequate substrates and encapsulating them. One of the most employed substrates for devices based on 2D materials is SiO₂, as it allows to easily find isolated layers of certain 2D materials by their optical contrast. However, the surface roughness of the SiO₂ and the existence of charged surface states limit the performance of the devices due to the scattering of charge carriers. Historically, this has had a negative impact on the mobility of graphene devices, with measured mobilities being much lower than the predicted values. hBN is a vdW material with a similar structure as that of graphene, but with the two C atoms of the unit cell being replaced by B and N atoms. The distinct B and N sublattices cause a lack of inversion symmetry that results in hBN having properties very different from those of graphene, being a dielectric vdW material with a large bandgap of ~6 eV. Moreover, hBN has a flat and inert surface free of charge traps, and with a small lattice mismatch with graphene (~1.8%). All this makes hBN an ideal candidate as a substrate for other 2D materials (Fig. 9A and B) (Decker et al., 2011). In particular, the mobility of graphene devices on hBN increases by almost an order of magnitude compared with devices on SiO₂ substrates (Fig. 9C). The performance of the devices can still be improved when the graphene is completely encapsulated by hBN, providing ballistic transport for distances of tens of microns and with record mobilities of ~1,000,000 cm²/Vs attained at low temperatures (<40 K). The mobilities obtained at room temperature for hBN-encapsulated graphene approach the theoretical predicted limits (Fig. 9D) (Wang et al., 2013). Slightly modest increases in mobility can also be observed when the graphene is encapsulated in certain vdW layered materials, such as TMDs. These increases in mobility are in part ascribed to the self-cleansing mechanism discussed above, and which is absent between the surface of the graphene and the SiO₂. Hence, similar improvements can be obtained when hBN is used to isolate other 2D materials (Fig. 9E) (Knobloch et al., 2021).

But although hBN can be considered as an excellent substrate for graphene, the interaction between both materials can significantly alter the electronic band structure of graphene. When the lattices of the graphene and the hBN are aligned or misaligned by just a small twist angle, the mismatch of their lattices causes an atomic reconstruction and the occurrence of moiré patterns with periods larger than those of the original lattices. The wavelength of the moiré superlattice can be obtained for any given twist angle according to Eq (1), with values $a = 2.46 \text{ \AA}$ and $\delta = 1.8\%$ for the lattice constant of graphene and the lattice mismatch between graphene and hBN, respectively. The effect of the periodic moiré potential in the band structure involves the appearance of additional Dirac points at low energies, and can even give rise to flat bands and correlated states similar to those described in the section about twisted bilayer graphene (Sun et al., 2021). This has led to the observation of phenomena like the Hofstadter butterfly spectrum (Fig. 10A) (Hunt et al., 2013), due to the 2D-confined electrons being subjected to the periodic moiré potential and to a high magnetic field, and of valley currents in the graphene at zero magnetic field (Fig. 10B) (Gorbachev et al., 2014). Additionally, the atomic reconstruction results in a breakage of the sublattice symmetry of graphene, inducing the opening of finite bandgaps of up to a few tens of meV at both the primary and secondary Dirac points. The discussed effects on the band structure of graphene can be further enhanced when the graphene is encapsulated in aligned hBN/graphene/hBN stacks. Similar to the case of TBG, the interaction between graphene and hBN can also be tuned by applying pressure to the heterostacks. This effectively decreases the interlayer distance and increases the interlayer coupling strength. When the graphene is aligned with one of the hBN layers the application of pressure can result in a two-fold increase of the moiré-induced bandgaps (Yankowitz et al., 2018).

TMD heterostructures

Of special importance is the case of vdW stacks of TMDs. The structure of TMDs, with the general formula MX₂, consist of two layers of a chalcogen element X (e.g., S or Se) with a transition metal layer M sandwiched in between (commonly Mo or W). Due to the broken inversion symmetry, most single layer TMDs are semiconductors with direct bandgaps ranging between 1 and 2 eV. However, the bandgap changes from direct for single layers to indirect for bi- or thicker homostacks, which have strong implications for the optoelectronic properties of the TMDs (Fig. 11A) (Ajayan et al., 2016). TMDs have strong optical absorptions of up to ~10% of the visible light for monolayer thickness, and up to ~40% for thicker flakes. For all these, TMDs are interesting candidates for ultrathin flexible optoelectronic devices.

Fig. 9 (A, B) STM images of an area of graphene on top of hBN, showing the topography (A) and the calculated charge density (B). The insets show the images of a graphene area of the same size but supported on SiO₂. (C) Resistivity and conductivity (left inset) of a graphene flake for areas supported on SiO₂ (red) and on hBN (black), for which the extracted carrier mobilities are 2000 cm²/Vs and 20,000 cm²/Vs, respectively. (D) Room temperature mobility of graphene encapsulated by hBN. The theoretical acoustic-phonon-limited mobility is included (dotted line), along with experimental mobility values of other 2D materials. The band alignment of most of TMDs heterostacks is of type II, with the maximum of the valence band and the minimum of the conduction band lying in different layers (Fig. 11B) (Rivera et al., 2018; Zhang et al., 2017). Holes and electrons can be produced in the heterostacks by photoexcitation, forming excitons (Coulomb-bounded electron-hole pairs) that then relax to their lowest energy states. As these states lie in different layers for each kind of carrier, there is a charge transfer across the junction with the carriers occupying different layers. The interlayer excitons have large binding energies owing to the small interlayer separation, while the separation is large enough for their lifetimes to be much larger than those of intralayer excitons. The high orbital velocities in the outer d-orbitals of the *M* heavy atoms induce a strong spin-orbit coupling. This results in splitting of the valence and conduction bands by a few hundred of meV and a few tens meV, respectively. These values depend on the specific TMD, with e.g., the band splitting being larger in WS₂ than in MoS₂. The conduction and valence band edges (valleys) of TMDs at the K points are energetically degenerate (+K, -K), and hence electrons have an additional degree of freedom. Optically generated interlayer excitons have valley polarization, retaining the circular polarization of the excitation light. This makes these heterostructures interesting for the future development of spintronic and valleytronic devices.

Photovoltaic devices can be realized in TMD heterostacks with the appropriate band alignments, as in the case of MoS₂ and WSe₂ to accumulate the electrons and the holes, respectively (Fig. 11C). Open circuit voltages of ~0.5 V can be obtained in such heterostacks. In conventional devices each layer is contacted in one side by an electrode, and hence carrier collection is done by the lateral diffusion of the carriers along their corresponding layers. The low mobility of TMDs results in the carriers remaining in the junction area for times of the order of the recombination lifetimes, hence decreasing the efficiency of photovoltaic cells with lateral electrodes. The efficiency can be improved by using graphene as vertical transparent electrodes (graphene/MoS₂/WSe₂/graphene). This allows for a faster collection of the carriers in the vertical direction and hence recombination is decreased (Lee et al., 2014). The efficiency can also be increased by increasing the thickness of the TMD layers. This leads to higher optical absorptions, although the photocurrent is in this case limited by lower charge collection and higher recombination rates.

The interlayer excitons in TMD heterostructures are also affected by the presence of the moiré superlattice. It is worth mentioning the occurrence of excitons trapped by the moiré superlattice in twisted heterostacks of TMDs (Seyler et al., 2019). The moiré pattern act as an array of quantum dot-like zero dimensional traps for the excitons. In the momentum space, the twist results in a separation of K valleys of the layers. This causes the optical transitions to change from direct to indirect with the introduction of a twist, resulting in increased interlayer exciton lifetimes with the twist angle (Choi et al., 2021). The control of the lifetime is interesting to further tune the properties of different optoelectronic devices, with light-emitting devices benefiting from the short lifetimes of the small twist angles.

Strain can also play an important role in the optoelectronic properties of the TMD heterostacks, specially for stacks in the regime of large moiré periodicities (Shabani et al., 2021). As the moiré wavelength increases for twist angles close to 0° or 60°, strain induced 1D soliton patterns can be observed in TMD stacks (Bai et al., 2020). At low energies, the excitons are confined within the 1D lines. Their broad, intense, and linearly polarized photoluminescence emission significantly differs from that of excitons trapped in hexagonal moiré lattices.

2D Heterostructures by intercalation

One of the current trends of vdW heterostructures consists in leveraging the interlayer space existing between the adjacent layers by the intercalation of different atoms or molecules (Ago et al., 2022). Given the nature of the interlayer interactions of vdW materials, there exists a clearly defined 2D nanospace between adjacent layers, typically ranging from 3 to 7 Å depending on the specific material. This space can be intercalated by foreign species that affect the physical properties of the host, allowing to further tune the properties of the heterostructure. The study of graphite intercalated compounds (GIC) has been conducted since 1841 (Dresselhaus and Dresselhaus, 2002), with the intercalation being a key role in the development of technologies such as anodes for Li-ion batteries. Only recently the concept of intercalation has begun to be studied for thin 2D materials.

Different metal chlorides have been intercalated in bilayer and in thin flakes of graphene, including FeCl₃, MoCl₅ and AlCl₃ among others. The charge transfer of these intercalants induces a doping that decreases the sheet resistance of BLG while keeping a high transparency (Fig. 12A). This makes intercalated BLG an interesting candidate for the fabrication of flexible transparent electrodes, competing in efficiency with conventional indium titanium oxide (ITO) based optoelectronic devices (Kinoshita et al., 2017). The degree of intercalation is affected by the twist angle of the BLG, providing a way to control the intercalation. The strong interlayer coupling at low twist angles makes intercalation difficult, while the intercalation is easier for large twist angles when the layers decouple. For polycrystalline samples in which the twist angle can vary across the surface, this allows to produce regions with differenced degrees of doping.

Alkali and alkaline-earth metals have also been intercalated in BLG. The emergence of superconductive states in bi- and few-layer graphene have been reported upon the intercalation of K, Ca and Li alkali or alkali earth atoms (Fig. 12B) (Ichinokura et al., 2016). Moreover, the reported densities can exceed those normally obtained in GIC. As an example, reversible superdense Li intercalation has been observed in BLG, with densities exceeding the LiC₆ expected for GIC (Fig. 12C-E) (Kühne et al., 2018). This opens the possibility to develop more efficient batteries with larger capacities.

The small thickness of the van der Waals heterostructures allows to study these intercalates with techniques that are not available for thicker intercalate compounds. This opens the possibility to get a more profound understanding of the mechanisms that govern the intercalation. The use of TEM has allowed to study the in-situ intercalation/deintercalation of alkali metals from solid

Fig. 12 (A) Schematics of BLG intercalated by MoCl₅, and the corresponding values for the transmittance and sheet resistance (red star). Values for other intercalants and of surface doping obtained from the literature are included for comparison. (B) Superconductive transition of Ca intercalated BLG (red curve), evidenced by a drop of the sheet resistance at temperatures below ~4 K. The sheet resistance of Li intercalated BLG is shown for comparison (blue curve). (C–E) Top and section views of the atomic models of Li intercalation into BLG. The insets to the top views represent the expected diffraction patterns for each of the structures. The contour plots in the section views represent the charge transfer between graphene and Li, with the blue and red representing increased and decreased electron densities, respectively. electrolytes into e.g., BLG and some TMDs (Fig. 13A). In the case of TMDs, the intercalation of alkali metals induces structural phase transitions that can depend on the twist angle (Fig. 13B–D) (Ji et al., 2021). By STEM, novel polymorphic phases have been described after intercalation of metal chlorides in BLG (Fig. 13E–G) (Lin et al., 2021c). Along with the higher densities of intercalant reported, these results point to the possibility to obtain new materials with exotic properties by the intercalation of 2D materials.

Characterization

Among the most prevalent methods of characterization of 2D materials and of vdW heterostructures are those based on their optical properties, including optical microscopy, and Raman and photoluminescence (PL) spectroscopy. These are usually fast, reliable, and non-destructive techniques that can provide information about the constituent layers, their thickness and stacking order, the presence of defects, contamination, and the degrees of doping and strain.

Optical microscopy is a direct method to identify the thickness of 2D materials. It is based on the increase of the optical absorption with the thickness, combined with interference effects arising from the thickness of the 2D material and the substrate

Fig. 13 (A) Schematics of the process for the in-situ TEM observation of the intercalation of Li into BLG. By applying differences of voltage between the electrolyte and the graphene, the Li can be reversibly intercalated (lithiation) and deintercalated (delithiation). (B–D) False colored ADF-STEM image of Li intercalated in non-twisted (area I) and twisted (area II) bilayer MoS_2 . As evidenced by the superlattice spots of each region (C, D), the region I underwent an H to T' phase transition upon intercalation whereas region II remained in the phase H. (E–G) Artificially colored STEM images of three different phases AlCl_3 phases that can be found when intercalated into BLG. (A) Reproduced with permission Kühne M. et al. (usually a thin SiO_2 layer on a Si substrate) and from their different refractive indexes (Li et al., 2013; Puebla et al., 2022) (Fig. 14). The small light absorption of the ultrathin 2D materials requires optimized substrates to provide high optical contrasts. In general, the contrast between a given 2D material and the substrate can be improved by choosing a suitable combination of the substrate (e.g., by altering the thickness of the SiO_2) and the wavelength of the incident light. As the contrast highly depends on the specific 2D material, there is no universal substrate that provides high optical contrast for all 2D materials. Thus, the widely used 300 nm thick SiO_2 provides reasonably good contrast for graphene, several TMDs and some other materials, but a very low contrast for hBN. The twist angle can also have a small effect on the optical absorption, and hence the optical contrast of vdW heterostructures can

Fig. 14 (A–C) Optical images of graphene (A), MoS₂ (B) and WSe₂ (C) flakes with different number of layers (indicated by red numbers), supported on 90 nm SiO₂/Si. The scale bars are 10 μm (A) and 5 μm (B, C). (A–C) Reproduced with permission Li H. et al. (2013) Rapid and reliable thickness identification of two-dimensional nanosheets using optical microscopy. *ACS Nano*, 7: 10344–10353. Copyright 2013, American Chemical Society.

slightly vary with it. As an example, optical differences are apparent for TBG with twist angles of $\sim 10\text{--}12^\circ$ under white light illumination. This method is however quite limited and cannot be used for the optical determination of the twist angle. In the case of 2D crystals with well-defined regular shapes, it is still possible to determine the twist angle from the alignment of the edges with an accuracy of $\sim 1^\circ$. But despite being a fast and simple method, optical microscopy offers limited information about the components of 2D heterostructures. It is thus commonly employed as a fast way to locate and estimate the thickness of the 2D materials for further characterization with other techniques.

Raman spectroscopy is a useful and common technique for the study of 2D materials, being fast, non-destructive, and providing a wide array of information. As an in-depth study of the technique and its application to 2D materials is out the scope of this book chapter, the reader is referred to Ferrari and Basko (2013) and Zhang et al. (2016) for more detailed information on the topic. Most 2D materials possess characteristic Raman spectra arising from their specific crystal structure, providing a way to determine the specific material and differentiate it from others. This makes Raman spectroscopy a useful tool to provide information about the specific components of vdW heterostructures. Variations in the shift, linewidth and relative intensity of the Raman bands can also provide information about the condition of the crystal, as the presence of defects, strain, or doping can alter the Raman spectrum in identifiable ways. Moreover, the Raman spectrum is also influenced by the interaction between the different layers. It is thus possible to determine additional information such as the thickness of each component, along with the twist angle or stacking order of the heterostructure, although the kind of information depends on the nature of the actual heterostructure. In the case TBG the evolution of the shape of the main Raman bands (named G and 2D), and of additional bands at low Raman frequencies arising from the coupling of the layers, can be used to determine the twist angle with even sub-degree accuracies for certain ranges of the twist angle (Barbosa et al., 2022) (Fig. 15A). For heterostructures of SLG and hBN the changes are more subtle but it is still possible to follow the twist angle by using Raman spectroscopy (Ribeiro-Palau et al., 2018). The Raman spectrum of TMDs stacks is also sensitive to the twist angle especially in the low-frequency regions corresponding to the breathing and shear interlayer modes (Lin et al., 2018, 2021a) (Fig. 15B and C).

For heterostructures including semiconducting layers, PL spectroscopy is another useful characterization technique. In the general case, the PL spectra of the heterostructure contain peaks corresponding to those of the layer that conform it. However, the interlayer charge transfer that can exist between layers tends to decrease the PL intensity. As pointed out in a previous section, the interaction between layers can also lead to the formation of interlayer excitons. These appear at lower energies than the original peaks, and for twist angles in which the layers are strongly coupled (Fig. 15D) (Nayak et al., 2017).

Concerning the atomic structure, several scanning probe (SPM) techniques including STM and different atomic force microscopy (AFM) modes are readily available. They can provide information about the atomic structure of the heterostructure, including the direct visualization of moiré patterns and of atomic reconstruction (Fig. 4A–C). The versatility of these techniques also allows to obtain sub-nanometer information about different physical properties of the heterostructures, including the electrical conductivity, the magnetic fields and the friction, as exemplified in Fig. 7 for the conductivity of an atomically reconstructed heterostructure and in Fig. 9A and B for the charge distribution. TEM-based techniques are also very extended, given the small thickness of the specimens. Similar to the case of SPM, the atomic structure of the heterostructures can be realized (Figs. 4D–O, and 6C–F). It is also possible to directly study the interface of the layers in cross-sectional TEM, as in Fig. 3D and I, allowing to obtain information about the number of layers, the stacking order and of the presence of foreign species in the interlayer spaces.

Traditional characterization techniques can be assisted by the use of robotic and machine-learning based methods, increasing the productivity and efficiency. Machine learning-based methods have been proposed to increase the efficiency and speed in the recognition and characterization of 2D materials and heterostructures by different methods. An example of this is the optical identification of exfoliated flakes mentioned in a previous section, which combined with the use of robotic systems can hugely

Fig. 15 (A) Average Raman spectra (532 nm excitation) of SLG and of TBG with different twist angles. The most characteristic Raman bands are labelled. (B, C) Low-frequency Raman spectra of bilayer MoSe₂ (488 nm excitation) (B) and of bilayer WSe₂ (532 nm excitation) (C) with different twist angles. (D) Room-temperature PL spectra of MoSe₂/WSe₂ heterostacks with different twist angles. The exciton peak positions of each layer are marked by vertical black dashed lines (the spectra of the individual layers are added for comparison). The interlayer exciton peak appears at lower energies (~1.35 eV, blue dashed line) for twist angles close to 0° and 60°. increase the throughput for the assembly of heterostructures. Machine-learning can also be used for fast and reliable identification and classification of different spectral signals, such as it can be the case of the Raman spectra for TBG (Solís-Fernández and Ago, 2022). On their side, the use of deep learning is relatively widespread in the case of TEM and STEM, helped by the maturity of image processing techniques based in convolutional neural networks (CNN) (Madsen et al., 2018). These are helpful to unravel the atomic structures, the presence of defects, and of strain, among other things, from collected experimental images.

Conclusion

Continuing with the trend of the 2D materials, the 2D van der Waals heterostructures is an emerging and relatively recent field. The integration of 2D materials into heterostructures opens new possibilities, and a plethora of novel physical phenomena has already been observed. But despite all the progress in recent years, a lot of effort is still needed to make it a technology that can be considered mature. Some of the current difficulties in developing vdW heterostructures are inherited from the still immature parent field of 2D materials, although they are compounded by the increased complexity of both handling heterostructures and understanding interlayer interactions. Theories that can predict and understand new physical phenomena brought about by 2D integration are still needed. This is evidenced by the lack of a completely satisfactory explanation for the superconducting states found in some twisted two-dimensional materials.

There are currently a few practical impediments for the industrial scaling and adoption of vdW heterostructures. The first is the obtention and processing of van der Waals heterostructures at larger scales. Existing dry-transfer methods for stacking 2D materials are suitable for scientific research and have led to major advances in the understanding of heterostructures at a fundamental level. However, these are mainly based on time consuming artisanal processes that are quite laborious and produce heterostructures with very limited areas. The integration of vdW heterostructures into industrial processes require a substantial increase in process automation, accompanied by the possibility to assemble wafer-scale homogeneous heterostructures. A first step toward this goal is the development of wafer-scale transfer techniques for as-grown 2D materials, along with efficient methods to arrange them into heterostructures, while maintaining qualities and homogeneities similar to those achieved by mechanical exfoliation at small scales. Eventually, the direct growth of large-scale heterostructures is a desirable achievement for industrial applications, potentially simplifying the processes involved in the assembly of heterostructures and alleviating many of the resulting problems. Although direct growth of heterostructures is currently mainly limited to heterostructures of hBN, graphene and some TMDs, low-temperature growth methods, such as by plasma assisted CVD, are promising for obtaining high-quality heterostructures with high qualities of diverse materials. The second challenge to overcome is the development of techniques for the fabrication and integration of vdW heterostructures into existing CMOS processing techniques. In this sense, the development of techniques for growing 2D materials at lower temperatures while maintaining their quality is especially crucial. Although a diverse selection of isolated electronic and optoelectronic devices with vdW heterostructures has been made, only limited effort has been made to produce integrated circuits consisting entirely of 2D materials and on wafer scales. Another current limitation for the industrial scaling is the lack of characterization techniques at wafer scales. Current existing methods are relatively slow and only allow the inspection of areas of limited sizes. As in the case of wafer defect inspection systems adopted by the industry, there is a need to develop wafer-scale characterization methods for 2D and related materials that enable rapid quality assessment with high sensitivity and spatial resolution.

Abstract

The meaning of Dirac's materials, in its most common sense, has been explored by taking a quick look at the Dirac equation, as originally formulated, and subsequently applied to the structure of condensed matter, of two-dimensional (2D) materials beyond graphene.

What makes 2D materials exceptional, as well as the discovery of new allotropic forms, is the possibility of having extraordinary physical properties, such as energy dispersion, which immediately can correlate electrons to their being Dirac fermions.

Through experimental and theoretical examples, we report structural and electronic properties of 2D materials beyond graphene, which today represent the frontier of condensed matter physics.

Introduction

The Dirac equation is the wave equation that describes the motion of fermions in a relativistically invariant way (Dirac, 1928). Born to describe massless particles with relativistic behavior, in 1928, it waited for several decades to be dusted off in the framework of the structure of matter, helping to award a Nobel Prize in physics (2010) to the two-dimensional (2D) atomic crystal (Novoselov et al., 2005a), currently the most famous in the world, graphene, a single layer of carbon (C) atoms arranged in a honeycomb lattice. 2D transition metal dichalcogenides (TMDs), such as MoS₂, MoSe₂, WS₂, MoTe₂, WSe₂, are naturally exfoliated, and today, largely artificially synthesized (Li et al., 2020, Lv et al., 2015, Samadi et al., 2018).

What made the difference and represented a significant increasing forward in the research of 2D synthetic materials, constituting a breakthrough in the field of condensed matter, was, first, the artificial synthesis of silicon in the graphene-like allotropic form (Vogt et al., 2012), experimentally realized, for the first time, on the oriented face of the single crystal Ag (111) (Vogt et al., 2012), paving the way for the search for other 2D elemental materials (Krawiec, 2018). This silicon allotrope, with Si atom arranged in a buckled honeycomb structure, not present in Nature, was already predicted in 1994, as a corrugated layer of Si, analogous to graphite (Takeda and Shiraishi, 1994). It was called silicene, by analogy to graphene in 2007 (Guzmán-Verri and Lew Yan Voon, 2007). Its electronic properties have been investigated, predicting electronic structure with Dirac cone, similar to graphene (Lebègue and Eriksson, 2009; Cahangirov et al., 2009).

Actually, as in the case of graphene, silicene, has remarkable physical properties, hosting Dirac fermions, as well as providing new template for a stacked growth of multilayer silicene (De Padova et al., 2013a,b, 2017), and opening the door to the family of synthetic 2D elemental materials (De Padova et al., 2022).

In the popular work “Two-dimensional gas of massless Dirac fermions in graphene,” the electron transport is basically described by the Dirac relativistic equation, where the charge carriers, both electrons and holes in their ambipolar behavior, in graphene, simulate the relativistic particles having *quasi* zero rest mass with an effective “speed of light” $c^* \approx 10^6 \text{ ms}^{-1}$, exhibiting the anomalous room-temperature quantum Hall effect, characteristic of two-dimensional Dirac fermions (Novoselov et al., 2004, 2005b).

Thus, a large family of materials, which include graphene and more generally the 2D materials, and *d*-wave superconductors, have in common the particularity that their fermions at low energy, near the Fermi level (FL), behave as massless Dirac particles that do not follow the Schrödinger classical Hamiltonian, but rather that of Dirac (Dirac, 1928). This new emergent class of materials identified with particular physical properties of condensed matter structure, is today called “Dirac materials.”

As it may concerns, it is necessary to consider the special features in the density of states (DOS) connected to the Van Hove singularities (Van Hove, 1953), whose wave vectors at which they occur are referred as critical points in the Brillouin zone (BZ). The so-called Dirac points in graphene, in the *k*-space, reciprocal space, to which Dirac cones are associated, are Van-Hove singularity, as well as in twisted graphene layers, showing pronounced Van-Hove singularities in the DOS due to the interlayer coupling (Bostwick et al., 2007; Brihuega et al., 2012; Ohta et al., 2006).

This expression, Dirac cone, derives directly from the energy bands of organized solids, where angular resolved photoemission spectroscopy (ARPES) (Kevan, 1992; Hüfner, 2010) is a very important spectroscopic technique for studying Dirac materials.

In graphene, and bilayer graphene (Bostwick et al., 2007; Ohta et al., 2006), the two special, inequivalent points, K and K', representing the apexes of the hexagon, in the *k*-space, where the filled, π , and empty, π^* bands, meet at the FL, in the Dirac points, with zero gap, causing energy bands dispersions cone-shaped. It is here that the structural form of atomic arrangement comes into play in close conjunction with the dispersion of the bands, and the realm of direct space, atomic structure, and electronic properties, energy band structure, takes on all its extreme importance. Scanning tunneling microscopy (STM), scanning tunneling spectroscopy (STS) and ARPES represent, in the direct and reciprocal space, respectively, the main characteristics, both of the surface crystal structure, atomic positions arrangement, and of the local- and long-range electronic properties, giving, these techniques, an immediate amazing ability in the study and classification of Dirac's materials.

The electrons, as well as holes, behave, neglecting all scattering phenomena as massless particles, travel undisturbed toward the FL, or toward a separating gap of the two Dirac cones associated with the filled and empty bands, respectively.

This inverse relationship between the direct and reciprocal space of matter has established an intimate relationship between the honeycomb-like atomic arrangement and Dirac's fermions, quasiparticles that follow the behavior dictated by Dirac equation and their precise position in 3D, 2D and 1D of *k*-space.

Thus, the search for artificial or natural 2D honeycomb-like materials constitutes a real extraordinary opportunity for the discovery of new physical properties of condensed matter that lead to intense research with the ultimate dual purpose both in the field of fundamental and applied physics. Monolayer topological insulators, giving rise to modern terms such as *spintronics* and *walleytronics*, new terms that refer to Dirac's innovative 2D materials, which could exploit novel electronic devices, based on these emergent physical properties of electronic structures (Ezawa et al., 2018).

Of a great importance, it is the spin orbit interactions, named also spin orbit coupling (SOC), which leads to quantum spin Hall effect (QSHE) in graphene, converting it to a quantum spin Hall insulator, from an ideal two-dimensional semi-metallic state (Kane and Mele, 2005a,b). This gives rise to a novel electronic state of matter, with time-reversal invariance, typically of the so-called topological insulator (TI) materials, gapped in the bulk and able to undisturbed transport the spin and charge in the gapless edge states propagating at the sheet boundaries (Kane and Mele, 2005a,b). These electronic states, close to the Fermi edge, are very important for their transport behavior. Due to their spin directionality, these states are protected, that is, imperturbable against the effect of exposure to foreign adatoms, as well as to intrinsic or extrinsic disorder and/or scattering processes (Kane and Mele, 2005a). In a strict sense, the QSHE occurs at the time-invariant points of the Brillouin zone, which is not the case in 2D honeycomb materials, like graphene. Nevertheless, similar state can still exist, and the edge states are robust against weak disorder and still contribute to the spin-Hall conductance (Kane and Mele, 2005a). Unfortunately in graphene the spin-orbit induced gap at the Dirac point, is extremely weak as $0.8 \times 10^{-3} \text{ meV}$, it is a second order process, occurring only at unrealistically low temperature (Yao et al., 2007).

In this work we will report on some impressive examples of the so-called systems, *par excellence*, Dirac materials, 2D materials beyond graphene. The most relevant experimental measurements and theoretical calculations of the current scientific research specific to this wonderful field of surface physics and, in general, condensed matter will be related. 2D elemental materials beyond graphene and TMD exfoliated and/or supported on template investigated through the main techniques, the heart of the investigation of the structure of matter, STM, STS, and ARPES, will be discussed.

Overview on Dirac materials beyond graphene

In addition to the QSHE in graphene, it was also proposed to obtain the QSH state, a state of matter with topological properties distinct from those of conventional insulators, in HgTe/CdTe quantum well, tuning the thickness of the HgTe layer, demonstrating, thus, that when the thickness of the quantum well is varied, at a critical value, the electronic bands at the time-invariant *k*-points

become inverted, thus exhibiting the QSH effect with a single pair of helical edge states (Bernevig et al., 2006). Just few time later, the QSH insulator state in HgTe quantum wells was experimentally observed, below liquid helium temperature (König et al., 2007).

Two-dimensional elemental topological insulators of group-IVA beyond graphene, including silicene, germanene (Liu et al., 2011a; Salomon et al., 2020), stanene (Liu et al., 2011b; Xu et al., 2013), and plumbene (Yu et al., 2017) are a new class of Dirac materials characterized by a predicted QSHE, exhibiting band gap generated from spin-orbit coupling with much larger SOC gap values, of 1.55 meV, for silicene, which makes it a robust TI up to ~ 15 K (Liu et al., 2011a); 23.9 meV for germanene and functionalized germanene (much higher than the liquid nitrogen temperature) (Liu et al., 2011a; Si et al., 2014), and ~ 100 meV for stanene (Xu et al., 2013), and ~ 200 meV for plumbene (Yu et al., 2017).

Very frequently, this gap makes these topological materials, electrically insulating in the atomic sheets (or bulk) and conductive with the edge of the sheets (or surface), which support the one dimensional (1D) topological edge states, possess quasiparticles obeying the Dirac equation, and having honeycomb-like atomic arrangement.

So far, to the 2D elemental materials beyond graphene of group-IVA, already presented, those belonging to group-III-VI, IVB [for exhaustive literature see Ref. (De Padova et al., 2022)] such as: borophene (Mannix et al., 2015), gallene (Tao et al., 2018) blue phosphorene (Zhang et al., 2016a; Gu et al., 2017), thallene (Gruznev et al., 2020), arsenene (Shah et al., 2020), antimonene (Lei et al., 2016; Jałochowski and Krawiec, 2019), bismuthene (Reis et al., 2017), selenene (Qin et al., 2017a), tellurene (Zhu et al., 2017), and hafnene (Li et al., 2013) have been recently synthesized, as well as theoretically predicted (Huang et al., 2014; Jin and Jhi, 2015).

To be more complete, a short mention to other emerging metal-enes, less realized but extremely interesting, such as Rh nanosheets (Duan et al., 2014; Zhao et al., 2015), monolayer goldene intercalated in graphene layers (Yuan et al., 2020), freestanding monatomic thick 2D Gold (Wang et al., 2019), iron membranes suspended in graphene pores (Zhao et al., 2014), which promise to exhibit remarkable physical properties.

Silicene is the oldest member of the graphene followers family. It was first synthesized on Ag(111) substrate (Vogt et al., 2012), and later also on surfaces of other crystals, ZrB₂(0001) (Fleurence et al., 2012), Ir(111) (Meng et al., 2013), ZrC(111) (Aizawa et al., 2014), Ru(0001) (Huang et al., 2017), and, as predicted in (Podsiadły-Paszkowska and Krawiec, 2015), on ultrathin Pb(111) (Stępnia-Dybala and Krawiec, 2019). Furthermore, we have to remark that supported germanene was successful synthesized on oriented (111) substrates such as: platinum (Li et al., 2014), gold (Dávila et al., 2014), aluminum (Derivaz et al., 2015), molybdenum disulfide (Zhang et al., 2016b), copper (Qin et al., 2017b) and silver (Lin et al., 2018).

Continuing further with Dirac's 2D elementary materials of group-IVA, recently discovered, the case of plumbene, a single atomic layer of Pb arranged in a honeycomb lattice, is also of great interest. As a strong analog of graphene, plumbene is expected to be a two-dimensional material with strong spin-orbit coupling effects.

From theoretical point of view, monolayer and bilayer plumbene were predicted (Huang et al., 2014; Rivero et al., 2014; Zhang et al., 2018), as well as a class of new QSH insulators, PbX (PbX; X = H, F, Cl, Br, and I), obtained decorating plumbene monolayers, exhibiting extraordinarily nontrivial giant-gap in the range of 1.03 to 1.34 eV (Zhao et al., 2016). Indeed, plumbene, as mentioned, was found to be a topological insulator with a large bulk gap (~ 200 meV) through electron doping (Yu et al., 2017), possible, for instance, using gate-tunable method (Yu et al., 2015), maintaining, thus, a robust nontrivial state with respect to external strain. Experimentally, a large area of plumbene was obtained, with success, by segregation process by depositing Pb thin films on Pd(111) (Yuhara et al., 2019), and a flat honeycomb Pb was synthesized on a Fe monolayer on Ir(111) interface (Bihlmayer et al., 2020).

Key issues on elemental 2D Dirac materials beyond graphene

As the family of Dirac materials discovered nowadays is very rich, including as mentioned, for instance, many groups- of the periodic table, -IIIA, IVA, VA-VI, and IVB, such as borophene, gallene, thallene, silicene, germanene, phosphorene, stanene, arsenene, antimonene, bismuthene, selenene, tellurene, hafnene, and TMDs, both in the form of elementary 2D materials and under that of composite compounds, we provide the essential crucial discoveries by separating them, in various paragraphs in the next section. The suffix-ene, in analogy to graphene, for the particular atom considered, represents its corresponding honeycomb-like lattice.

From each group of the periodic table of elements we take the significant works that highlight both theoretical calculations and experimental results underlining the importance of the ARPES, STM, and STS to study the electronic properties in conjunction with their relevant atomic honeycomb structures.

$(3 \times 3)/(4 \times 4)$ silicene on Ag(111), planar silicene on Au(111)/Si(111), and $(\sqrt{3} \times \sqrt{3})R30^\circ$ multilayer silicene

The following three paragraphs summarize the main results obtained on silicene and multilayer silicene grown on different substrates.

$(3 \times 3)/(4 \times 4)$ silicene on Ag(111)

From theoretical point of view silicene and germanene were predicted to assume honeycomb-like arrangement, although, unlike in graphene, with two sublattices displaced vertically, making the structures not completely planar, as illustrated in Fig. 1 However, planar forms have also been predicted (Cahangirov et al., 2009). In spite of the buckled geometry, the electronic properties

Fig. 1 Structural model of a freestanding 2D honeycomb-lattice material in its low-buckled form. Panels (a)–(c) show perspective, top and side views. Two sublattices separated vertically by Δ (c) are marked by different colors. The unit cell is indicated in (b). Adapted from Fig. 1 of Krawiec M (2018) Functionalization of group-14 two-dimensional materials. *Journal of Physics: Condensed Matter* 30: 233003–29.

characteristic of graphene are preserved and express electronic structures with Dirac cones at K and K' points, of hexagon in the reciprocal space, hosting the π - π^* Dirac bands with linear behavior (Takeda and Shiraishi, 1994; Guzmán-Verri and Lew Yan Voon, 2007; Lebègue and Eriksson, 2009; Cahangirov et al., 2009).

Furthermore, owing to the buckling and mixed sp^2/sp^3 bonding, silicene is more chemically active than graphene. This feature can be recognized as an advantage, as it allows for quite easy functionalization by different means (Krawiec, 2018). For example, the energy gap in the energy spectrum can be open and tuned by external electric field (Ni et al., 2012; Drummond et al., 2012), which has led to the fabrication of the first field-effect transistor based on silicene (Tao et al., 2015).

Experimentally, the fascinating proof for the first graphene-like 2D silicene was successful achieved in its prototypical $(3 \times 3)/(4 \times 4)$ reconstruction, on Ag(111) single crystal, by depositing Si in UHV, at a temperature of about 490 K (Vogt et al., 2012). Subsequently, numerous authors synthesized silicene on Ag(111) and others on different substrates (Aizawa et al., 2014; Du et al., 2014; Feng et al., 2012; Fleurence et al., 2012; Huang et al., 2017; Lin et al., 2012; Meng et al., 2013; Stepniak-Dybala and Krawiec, 2019; Stepniak-Dybala et al., 2019).

The salient electronic and structural characteristics of $(3 \times 3)/(4 \times 4)$ silicene epitaxially grown on Ag (111) [the (3×3) silicene unit cells coincide with a (4×4) Ag(111)] (Vogt et al., 2012), are described in the following.

Fig. 2(a) shows the ARPES dispersions from the $(3 \times 3)/(4 \times 4)$ silicene on Ag(111) measured along the Ag $\bar{\Gamma} \rightarrow \bar{K}$ direction through the $\bar{K}^{\text{Si}}$ silicene point. The BZ scheme, where the red arrow indicates the ARPES measurement direction, is reported in Fig. 2 (b). Panels (c)–(e) display the filled-states STM images of clean Ag(111) (1×1) and the flower-like $(3 \times 3)/(4 \times 4)$ silicene, while the model of silicene on Ag(111), obtained from DFT calculations, is depicted in (e). The larger orange balls denote the Si atoms directly sit on top of Ag atoms; the smaller ones those located between the Ag atoms, and the gray balls the substrate Ag atoms. In addition, the ball-and-stick model for the freestanding silicene is displayed in the bottom right panel (e) corner.

Very interestingly, the ARPES energy dispersions vs. the parallel momentum, collected at the special point $\bar{K}^{\text{Si}}$ (a) of the smaller (1×1) silicene hexagon scheme of the first BZ (b), that of Ag(111) (1×1) in the reciprocal space is also shown, along the Ag $\bar{\Gamma} \rightarrow \bar{K}$ direction, displays a linear dispersion (Vogt et al., 2012). This linear dispersion, showing a velocity of $\sim 1.3 \cdot 10^6 \text{ m s}^{-1}$ similar to that of graphene (Novoselov et al., 2005b), was attributed to the π branch of a silicene Dirac cone, pointing to massless Dirac fermions in silicene (Vogt et al., 2012). The band seems to disappear at $\sim 0.3 \text{ eV}$ below the Fermi level EF, so that an energy gap of approximately 0.6 eV, between the π and π^* silicene bands was deduced (Vogt et al., 2012). The (3×3) reconstruction of silicene induced band folding, leading to cone-like structures at $\bar{\Gamma}_{00}$, as well as at Ag $\bar{M}$, which is the $\bar{\Gamma}_{02}$ point along $\bar{M}-\bar{\Gamma}-\bar{M}$ direction of the (3×3) reconstructed silicene BZ (Avila et al., 2013).

Although this assignment of the silicene π structure was debated, trying to not assigning any Dirac fermion character caused by the supposed hybridization between the Si and Ag bands (Guo et al., 2013), other groups affirmed, by first-principles calculations and taking into account the influence of the Ag substrate, the presence of Dirac fermions with a finite band gap (Huang et al., 2013), and nevertheless the hybridization with the silver bands, related to the specific $(3 \times 3)/(4 \times 4)$ silicene reconstruction (Cahangirov et al., 2013).

Furthermore, the presence of the silicene linear band at $\bar{K}^{\text{Si}}$ (Vogt et al., 2012), crossing indeed the FL, probably related to a different silicene/Ag coverage ratio leading to silicene doping, and the Dirac cone at Ag $\bar{M}$ point, with interesting characteristic of saddle point, given to a possible anisotropic electron delocalization, were confirmed as belonging to the $(3 \times 3)/(4 \times 4)$ silicene (Tsoutsou et al., 2013). Notably, six pairs of Dirac cones, located at the $\bar{K}^{\text{Si}}$ of the (3×3) reconstructed silicene BZ have been measured by ARPES (Feng et al., 2016). We note that the substrate temperature is an important issue for the growth of $(3 \times 3)/(4 \times 4)$

Fig. 2 ARPES dispersions at $h\nu = 126$ eV from the $(3 \times 3)/(4 \times 4)$ silicene on Ag(111) measured along the Ag $\bar{\Gamma} \rightarrow \bar{K}$ direction through the $\bar{K}$ silicene point (a); BZ scheme where the red arrow indicates the ARPES measurement direction (b); filled-states STM images of clean Ag(111) (1×1) (c); STM of the 4×4 silicene (d); model of silicene on Ag(111): the larger orange balls denote the Si atoms sitting on top of Ag atoms; the smaller balls those located between the Ag atoms, and the gray balls the Ag atoms (e). The ball-and-stick model for the freestanding silicene layer is displayed in the bottom right corner of (e). Adapted from Fig. 3 and Fig. 4 of Vogt P, De Padova P, Quaresima C, Avila J, Frantzeskakis E, Asensio MC, Resta A, Ealet B, and Le Lay G (2012) Silicene: Compelling experimental evidence for graphenelike two-dimensional silicon. *Physical Review Letters* 108: 155501–5.

silicene, exhibiting Dirac fermion features (Liu et al., 2014b; Fukaya et al., 2013). They used linear dichroism ARPES, in addition to tight-binding model, and first-principles calculations, to attest that these six pairs of Dirac cones mainly derived from the original cones at the $\bar{K}$ ($\bar{K}'$) points of free-standing silicene (Feng et al., 2019), splitted by the external periodic potentials originated from the substrate-overlayer interaction (Feng et al., 2019), confirming the origin of the Dirac cones in the (3×3) silicene/Ag(111) (Vogt et al., 2012).

From proposed structural model, the Si atoms located directly on top of Ag atoms are displaced in z direction with respect to those at the bottom. The distance between the top (bottom) Si atoms and the first silver layer is of 0.292 and 0.217 nm (Vogt et al., 2012), giving, interestingly, to the silicene sheet, a buckling of 0.075 nm between the orange and yellow Si atoms as marked in Fig. 2(e).

Planar silicene on Au(111)/Si(111)

While the planar form of the isolated silicene was predicted to be dynamically unstable (Cahangirov et al., 2009), it can exist when placed on a substrate, as demonstrated in the case of thin Au slab on the Si(111) (Stepniak-Dybala et al., 2019). It has been shown that ultimately flat layer of Si atoms arranged in a honeycomb lattice, as evidenced in Fig. 3, can be synthesized in the process of the surface segregation. The exceptionally low buckling, an order of magnitude lower than in the free-standing form, is a consequence of significant interaction between Si and underlying Au atoms.

This is also responsible for deformation of hexagons, making the silicene lattice substantially strained (Nazzari et al., 2021). In addition to that, the continuous layer of the planar silicene undergoes long-range structural deformations, similar to graphene.

In the case of Au/Si(111) substrate the planar silicene is a part of a more complex heterostructure containing also twisted buckled phase of silicene (Jaroch et al., 2021), and may serve as a platform for developing 2D magnetism (Krawiec et al., 2021).

$(\sqrt{3} \times \sqrt{3})R30^\circ$ multilayer silicene/Ag(111)

Multilayer silicene, showing the evidence of Dirac fermions, was predicted beyond silicene monolayer both in bilayer and different stacking configurations (Hoffmann, 2013; Kamal et al., 2013; Cahangirov et al., 2014), and realized (De Padova et al., 2013a) in the $\sqrt{3} \times \sqrt{3}R30^\circ$ reconstruction on top of the $(3 \times 3)/(4 \times 4)$ monolayer silicene (Vogt et al., 2012), with a growth that proceeds by successive flat terraces separated by ~ 3 nm and a unit cell of ~ 0.64 nm (De Padova et al., 2013a; Vogt et al., 2014).

Fig. 3 (a) Atomically resolved STM image of planar silicene on Au(111) thin films on Si(111) substrate. (b) 2D Fourier transform of the STM image shown in (a). (c) Topography profile along the line marked in (a). Adapted from Fig. 2 of Stępniań-Dybala A, Dyniec P, Kopciuszynski M, Zdyb R, Jałochowski M, Krawiec M (2019) Planar silicene: A new silicon allotrope epitaxially grown by segregation. *Advanced Functional Materials* 29: 1906053–5.

Numerous other experimental evidences have been reported on synthesis of multilayer silicene (De Padova et al., 2013a,b, 2014, 2016; Du et al., 2016; Grazianetti et al., 2017; Li et al., 2016; Salomon et al., 2014; Vogt et al., 2014), although a debate existed if this $\sqrt{3} \times \sqrt{3}$ R30° reconstruction was, indeed, induced by Ag atoms on Si(111) (Shirai et al., 2014).

Clear evidence of the synthesis of multilayer silicene was provided by a study done using x-rays, where the characteristics of ordinary silicon and multilayer silicene are clearly distinguished (De Padova et al., 2016). The discrepancy of the conflicting results, reported in the literature, is most likely attributable to the preparation of the samples, being the temperature applied to the substrate and the flow of the silicon cell for evaporation, the fundamental ingredients for the formation of the silicene multilayer or ordinary silicon.

Moreover, recently the multilayer silicene has been realized on other templates such as Si covered with Ag or Bi atoms (De Padova et al., 2017, 2019; Garagnani et al., 2022). Very interestingly a model performed with DFT calculations for three layer silicene grown on Ag-Si(111) template with AA'B stacking was successfully proposed (De Padova et al., 2017).

It should also not be forgotten that in addition to the transistor made using a silicene monolayer (Tao et al., 2015), one based on silicene multilayer was also designed and produced (Grazianetti et al., 2017).

Thus, It is extremely interesting to report the case of multilayer silicene on Ag(111), where the presence of the Dirac cones excellently assign to this new allotrope of silicon a good example of Dirac material. In fact, the following Fig. 4 shows some characteristics that highlight the electronic properties of the silicene multilayer (4.5 MLs silicene layers) epitaxially grown on top of first $(3 \times 3)/(4 \times 4)$ monolayer on Ag(111) (De Padova et al., 2013a).

ARPES pattern in Fig. 4(a) was collected by using a synchrotron radiation photon energy of 126 eV, along the $\bar{\Gamma} \rightarrow \bar{K}^{\text{silicene}}$ on the $\sqrt{3} \times \sqrt{3}$ R30° multilayer silicene, its waterfall line profiles is displayed in Fig. 4(b), as a guide for the eyes (De Padova et al., 2013a).

The energy band dispersion clearly shows the linear $\wedge$ and $\vee$ shape at $\bar{\Gamma}_0$, where the $\bar{K}_{(1 \times 1)}^{\text{silicene}}$ and $\bar{K}_{(1 \times 1)}^{\text{silicene}}$ bands fold, as drawn in the BZs scheme of Fig. 4(c) giving rise to the Dirac cones (De Padova et al., 2013a). These linear bands were assigned to the π and π^* of the $\sqrt{3} \times \sqrt{3}$ R30° multilayer silicene, with the π^* state are partially filled by the charge transfer from Ag substrate, no gap between the π and π^* bands and their crossing at Dirac point—0.25 eV (De Padova et al., 2013a). This electronic features exhibit at RT a Fermi velocity of $\sim 0.3 \cdot 10^6 \text{ m} \cdot \text{s}^{-1}$ (De Padova et al., 2013a) only a bit smaller to that found by STM quantum interference pattern at low temperature (Chen et al., 2012). In addition, the inner structure inside the more external π cone is related to the presence of the (1×1) silicene layer in its successive terraces growth. Moreover, to show the Dirac features along the other six $\bar{\Gamma}$ points (from $\bar{\Gamma}_1$ to $\bar{\Gamma}_6$) of the $\sqrt{3} \times \sqrt{3}$ R30° multilayer silicene, the Fig. 4(d) displays the dispersion pattern vs. the azimuthal angle, very well evidencing all the linear bands belonging to multilayer silicene, in addition to the sp silver bands (De Padova et al., 2013b). Here, the constant energy contour obtained on the $\sqrt{3} \times \sqrt{3}$ R30° multilayer silicene, evidencing the characteristics of the Dirac cones, have been amply studied. In Fig. 4(e) there is the scheme of the Dirac cone cut, along with the dispersion measured (De Padova et al., 2013b).

The case of Stanene on supported substrates: Buckled Stanene/InSb(111) and flat Stanene/Cu(111)

The following two paragraphs summarize the main results obtained on buckled and flat stanene grown on InSb(111) and Cu(111) substrates.

Fig. 4 ARPES Dirac cones of $\sqrt{3} \times \sqrt{3}$ R30° multilayer silicene and (1×1) silicene layer measured at $\bar{\Gamma}_0$ along the $\bar{\Gamma} \rightarrow \bar{K}^{\text{silicene}}$ direction ($h\nu = 126$ eV) showing linear π and π^* bands (a), scheme of the surface Brillouin zones (b), and the waterfall line profiles of (a), as a guide for the eyes (c); the Dirac dispersion pattern vs. the azimuthal angle along the six $\bar{\Gamma}$ (from $\bar{\Gamma}_1$ to $\bar{\Gamma}_6$) points of the $\sqrt{3} \times \sqrt{3}$ R30° multilayer silicene is reported in (d), and scheme of the Dirac cone cut, along with the dispersion was measured is in (e). Buckled Stanene grown on InSb(111)

Within the topological insulator materials, the new state of quantum matter, we must mention a monolayer of tin film called stanene, in analogy with graphene, germanene and silicene. It was proposed as a large-gap quantum spin Hall insulator, supporting QSH and quantum anomalous Hall (QAH) states predicted at near room temperature (RT) in honeycomb materials (Xu et al., 2013).

Based on first-principles calculations, stanene performed its entry into 2D materials, exhibiting, in freestanding stanene, a gap value of ~ 100 meV, sufficiently large for any practical applications at RT (Liu et al., 2011b; Wu et al., 2014; Xu et al., 2013). In addition, their QSH states were found tunable up to an extraordinary gap of ~ 300 meV, through chemical functionalization by halogen atoms adsorption and/or applying an external strain (Xu et al., 2013).

The optimal geometries for freestanding stanene and freestanding decorated stanene present a low-buckled configuration found more stable, at variance of planar geometry of graphene. This is due to the relatively weak Sn-Sn π - π bonding, thus the buckling stabilizes the system, enhancing the overlap between the σ and π tin orbitals (Xu et al., 2013).

In 2015, the breakthrough experiment, verified, for the first time, as the growth of a single-layer of buckled stanene, material previously largely theoretically predicted, on $\text{Bi}_2\text{Te}_3(111)$ by molecular beam epitaxy (MBE) (Zhu et al., 2015), opening the way to the search of other suitable templates.

Honeycomb stanene in buckled and/or planar structure was, thus, deposited by MBE on several substrates such as semi-metallic Sb(111) (Gou et al., 2017), PbTe(111) (Zhang et al., 2018), InSb(111) (Xu et al., 2018), Ag(111) (Yuhara et al., 2018), Cu(111) (Deng et al., 2018), Au(111) (Liu et al., 2019), and Sb_2Te_3 (Li et al., 2020b), demonstrating its successful synthesis.

Stanene grown on the surface of InSb(111) is a classic case in which the Sn honeycomb lattice exhibits a buckling (Xu et al., 2018). Single Stanene layer was epitaxially grown by MBE on the surface of InSb(111)B face (Sb terminated) at RT (Xu et al., 2018). Following the intensity of the reflection high energy electron diffraction (RHEED) pattern, during the Sn atoms deposition, stanene was grown on the typical 3×3 RHEED pattern of InSb substrate. This substrate reconstruction was completely modified to a 1×1 pattern, belonging to stanene, upon the deposition of one layer of tin. At variance of graphene and/or graphite, which exhibit planar sp^2 bonding, the gray tin, often called α -tin, is characterized by sp^3 bonding, attributing to its honeycomb structure a lattice buckling.

As shown in Fig. 5(a), which reports top and side views of the schematic atomic structure of the honeycomb stanene, and Fig. 5(b), showing the side view of its buckled atomic structure, including in addition four layers of the InSb substrate Sb terminated, stanene, here, is not flat like graphene. The optimized structure obtained by first principle calculations determined a vertical spacing of 2.85 Å to the down-buckled Sn atoms that lied on top of the surface Sb sites of InSb, as indicated in Fig. 5(b). The buckling found

Fig. 5 Schematic atomic structure of the buckled honeycomb stanene, top and side views (a); atomic structure of stanene on InSb(111), side view (b); BZ of stanene (c); ARPES from InSb(111) substrate (d) and from Sn/InSb(111) (e) along the high-symmetry $\bar{\Gamma}\bar{K}$ and $\bar{\Gamma}\bar{M}$ directions, respectively. The bands of the heavy hole (HH) and light hole (LH) are indicated. Calculated stanene band structures considering six InSb(111) layers are shown in (f). The top and the bottom of the valence (VB) and conduction bands (CB) are also marked, whereas, the Fermi level was set at the conduction band bottom. Adapted from Fig. 1 and 2 of Xu CZ, Chan YH, Chen P, Wang XX, Flötotto D, Hlevyack JA, Bian G, Mo SK, Chou MY, and Chiang TC (2018). Gapped electronic structure of epitaxial stanene on InSb(111). *Physical Review B* 97: 035122–5.

on this honeycomb lattice of stanene leads unaffected the BZ displayed in Fig. 5(c), where the high-symmetry $\bar{\Gamma}\bar{K}$ and $\bar{\Gamma}\bar{M}$ directions are indicated.

As we can easily observe from Fig. 5(d), the ARPES structures of InSb(111) surface, show the characteristic heavy hole (HH) and light hole (LH) features along the two high-symmetry $\bar{\Gamma}\bar{K}$ and $\bar{\Gamma}\bar{M}$ directions, reaching at $\bar{\Gamma}$ point the Fermi level, set at the conduction band bottom, corresponding to a lightly n-doped substrate (Xu et al., 2018).

Interestingly enough, after the stanene formation on InSb(111) surface, the ARPES dispersions, displayed in Fig. 5(e), drastically modified, pushing down the top of valence band, opening, therefore, a large gap of about 0.44 eV (Xu et al., 2018). Fig. 5(f) reports the calculated band structures of the honeycomb stanene, including the two top layers of the InSb substrate. These band structures were found, in good agreement with the experiment, confirming that stanene on InSb(111) is an insulator exhibiting a large gap value of 0.44 eV (Xu et al., 2018). Compared to the calculated band gap for freestanding stanene, which was of only ~ 0.1 eV (Xu et al., 2013), this enhanced band gap was interpreted due to the interaction established between stanene and substrate atoms, similarly to what occurs when halogens are adsorbed on freestanding stanene, then, inducing gap widening (Xu et al., 2013).

This gap for stanene results much larger than the RT thermal energy $k_B T = 25$ meV, attesting that the stanene film grown on InSb could be a promising candidate for QSH applications at RT and/or higher (Xu et al., 2018).

Flat Stanene grown on Cu(111) substrate

In Fig. 6 the results obtained in stanene grown on Cu(111) substrate by low-temperature molecular beam epitaxy are reported, where, interestingly, an ultra-flat honeycomb stanene, graphene-like, exhibiting topological features was discovered (Deng et al., 2018).

The Sn atoms (0.9 ML) were deposited in UHV by Knudsen effusion cell on Cu(111) substrate kept at about 200 K. For STM and STS measurements the Sn/Cu(111) was, successively, cooled to 5 K. After Sn deposition, the Cu(111) substrate resulted mainly covered by an uniform and continuous Sn film, except for a small part of substrate, giving the possibility to trace a profile, which shows an apparent height of the Sn film of 0.18 nm, pointing to a single Sn atomic layer (Deng et al., 2018). The high-resolution STM image from Sn on Cu(111), see Fig. 6(a), shows an impressive stanene honeycomb lattice, whose schematic atomic model is presented in Fig. 6(b). The line profile reported in Fig. 6(c), obtained along the blue line traced in the STM image in Fig. 6(a), evidenced clearly that adjacent Sn atoms have an identical apparent height, with a Sn-Sn distance of 2.94 Å. From the STM image a lattice constant of 0.51 nm is derived, which is exactly twice that of the Cu(111) surface ($a_{\text{Cu}}/\sqrt{2} = 0.361/1.414 \text{ nm} = 0.255 \text{ nm}$), pointing to a formation of a 2×2 stanene superstructure. The marked unit cell of this ultra-flat honeycomb stanene includes the two inequivalent Sn atoms, with Sn-Sn bond length very similar to that of bulk α -Sn of 2.81 Å and/or 2.83 Å attributed to freestanding stanene (Xu et al., 2013).

Fig. 6 Atomic resolution STM image of the stanene film on Cu(111) ($V_s = 1$ V, $I = 0.4$ nA) (a), a lattice constant of 0.51 nm is marked; schematic atomic model of the honeycomb stanene (b); profile along the blue line traced in (a), evidencing that the adjacent Sn atoms have an identical apparent height, with a Sn-Sn distance of 2.94 Å. ARPES map of 0.9 ML stanene on Cu(111) along the $\overline{M}\overline{\Gamma}\overline{M}'\overline{\Gamma}_2$ paths (d), following the green line in (e) is displayed. In (e) is outlined the BZ of Cu(111) (blue), and the 2×2 superstructure hexagons of stanene. The orange lines in the ARPES map are the energy bands of Sn orbitals, whereas at $\overline{\Gamma}_2$ point new Sn bands with a gap of 0.3 eV are clearly present. Adapted from Fig. 1 of Deng J, Xia B, Ma X, Chen H, Shan H, Zhai X, Li B, Zhao A, Xu Y, Duan W, Zhang S-C, Wang B, and Hou JG (2018) Epitaxial growth of ultraflat stanene with topological band inversion. *Nature Materials* 17: 1081–1086.

ARPES map of 0.9 ML stanene on Cu(111) (Deng et al., 2018) along the $\overline{M}\overline{\Gamma}\overline{M}'\overline{\Gamma}_2$ paths is displayed in Fig. 6(d), following the green line marked in panel (e), where is outlined the BZ of Cu(111) (blue), and the 2×2 hexagons of stanene. The orange lines in the ARPES data are attributed to the energy bands of Sn orbitals. At $\overline{\Gamma}_2$, in the second BZ, a significant gap opening in the Sn bands, centered at around -1.25 eV, with a value of 0.3 eV is clearly evident, more than in $\overline{\Gamma}$, presenting analogies to the p_{xy} orbitals and large SOC gap predicted for fluorine atoms adsorbed on stanene (Xu et al., 2013). Interestingly, first-principles calculations revealed the delicate role played by the stanene lattice stretching, in conjunction to the strong substrate interactions that are important to stabilize the amazing zero-buckling geometry in stanene/Cu(111), creating this honeycomb lattice p_{xy} orbitals mediated by orbital filtering effect of Cu substrate. The discovered in-plane s - p band inversion mechanism in communion to the large SOC justified this topological gap here found, at the $\overline{\Gamma}$ point (Deng et al., 2018).

It is also extremely important to note that the topologically derived edges states, as predicted by the theory (Xu et al., 2013), have been observed (Deng et al., 2018), making this ultra-flat honeycomb stanene the seed-platform for the observation of physical phenomena typical of Dirac's 2D materials.

Remarkably, remaining in the frame of planar honeycomb stanene, we also mention the results obtained on epitaxially grown stanene/Ag (111), where the electronic structures exhibited the characteristic surface 2D parabolic dispersion, and any evident presence of spin-orbit -coupling effect, fact that attributed to the strong interaction with substrate, hosting, before stanene honeycomb condensation, an underlying 2D Ag_2Sn surface alloy (Yuhara et al., 2018).

The case of bismuthene

As a representative of 2D material of the group-VA, we report the supported $\sqrt{3} \times \sqrt{3}$ R30° bismuthene, synthesized on the SiC(0001) substrate in a planar configuration.

Ultra-flat bismuthene on SiC(0001)

The scheme of planar $\sqrt{3} \times \sqrt{3}$ R30° bismuthene layer placed on the threefold-symmetric SiC(0001) substrate is illustrated in Fig. 7(a). Combining theory and experiment, the bismuthene on SiC(0001) system was found to represent a *quasi*-2D topological insulator, with large QSH gap, determined by strong SOC (Reis et al., 2017).

The high resolution filled-states STM image of Fig. 7(b), shows the bismuthene characteristic honeycomb pattern (Reis et al., 2017), whereas the DFT band-structure calculations, performed with the hybrid exchange-correlation functional including SOC (Liu et al., 2014a) are displayed in Fig. 7(c), showing at the $\bar{\Gamma}$ point a direct energy gap of 1.06 eV, much larger than in graphene, which was calculated to be about 10^{-3} meV (Yao et al., 2007). The conduction band at $\bar{\Gamma}$ has a wide indirect band gap $E_{\text{gap}} = 0.67$ eV, marked by the dashed lines in DFT bands. In conjunction ARPES measurements are displayed in Fig. 7(d) and the surface BZ scheme in Fig. 7(e). ARPES band dispersion, the zero of energy (E_F) was aligned to the Fermi level of the spectrometer, was probed along the critical points $\bar{\Gamma}$, $\bar{K}$, $\bar{M}$ of the SBZ of Fig. 7(e). Clearly the maximum of the valence band and the large band splitting of about 0.43 eV at $\bar{K}$ point, identified as the Rashba fingerprint of the system (Reis et al., 2017), are in very good agreement with the theoretical calculations reported in Fig. 7(c) (Reis et al., 2017). By STS measurements conductive edge states were stimulatingly probed (Reis et al., 2017), constituting together to the results reported on stanene/Cu(111) (Deng et al., 2018) an excellent platform for the conductive topologically derived boundary states (TDSs) (Reis et al., 2017).

Very interesting, this archetype work demonstrated the importance of the substrate in controlling the orbitals in 2D QSH insulator (Reis et al., 2017). Actually, in the bismuthene on SiC(0001), the physical mechanism for rising the QSH gap and controlling the not trivial topological invariant, is different from graphene (Kane and Mele, 2005a), where the gap emerges from the SOC between next-nearest neighbors, and it is, as mentioned, a second order process, and/or other 2D material of group-IVA, such as silicene, although with larger gap, where the SOC is still next-nearest-neighbor type, having as relevant orbital the p_z character. At variance, in bismuthene on SiC, their low-energy electronic properties are piloted by an huge on-site SOC p_x and p_y orbitals (Reis et al., 2017; Liu et al., 2014a). In addition, to the large atomic (on-site) SOC related to heavy Bi atom, there is also the interaction with substrate, due to the large lattice parameter assumed by planar, without buckling, strain-free bismuthene in the epitaxial growth on SiC(0001) (Reis et al., 2017). Further evidence of the importance of the occurrence of strain, external induced or due to the epitaxial growth, is given by the case of functionalized stanene, where QSH states can be effectively tuned by chemical functionalization and by external strain (Xu et al., 2013); and/or compressed germanene synthesized on MoS₂ (Zhang et al., 2016b).

Fig. 7 Scheme of planar $\sqrt{3} \times \sqrt{3}$ R30° a bismuthene layer placed on the threefold-symmetric SiC(0001) substrate (a); high-resolution STM filled-states image, providing the bismuthene honeycomb structure (b); DFT band-structure calculations for monolayer bismuthene on SiC(0001) (c) compared to ARPES data (d); surface BZ of the Bi hexagonal lattice (e). Brief summary on 2D-TMDs

Nowadays, others two-dimensional materials likewise transition metal dichalcogenides have pushed the research toward a new conception of nanoelectronics and optoelectronics owing to their amazing physical properties (Wang et al., 2012). At variance of graphene, the TMDs can be considered as consisting of a sandwiched structure of a transition metal layer (such as Mo, W, Nb) between two chalcogen layers (such as S, Se, Te).

These are, layered materials with strong in-plane σ and very weak out-of-plane π bondings, exhibiting van der Waals interactions, facilitating their exfoliation in single- and multi-2D layers and/or their atomic condensation, through evaporation methods, generally irrespective of any rigorous substrate epitaxy matching.

Thus, although the TMDs have been explored for long time, recent advances in nanoscale materials control, characterization and device assembly have opened to these stacked van der Waals 2D materials new opportunities to investigate features related to charge transfer and photon–exciton interactions (Butler et al., 2013), and to exhibit chemical properties very versatile (Chhowalla et al., 2013).

Molybdenum disulfide (MoS_2) (Splendiani et al., 2010) and tungsten disulfide (WS_2) (Cong et al., 2014) are, for instance, very fascinating among the 2D TMDs, exhibiting sizable band gaps that change from indirect to direct in single layers (Cong et al., 2014; Mak et al., 2010) opening the door to their applications in photoelectronics (Choi et al., 2013; Lee et al., 2012).

A new class of large-gap QSH insulators in 2D TMDs with $1T'$ structure, i.e., $1T'$ -MX₂ with M = W or Mo and X = Te, Se, or S, was predicted, by using first-principles calculations (Qian et al., 2014).

The monolayer TMDs–MX₂ keep polytypic structures type 1H, 1T, and $1T'$ (Eda et al., 2012; Heising and Kanatzidis, 1999; Qian et al., 2014; Wilson and Yoffe, 1969), where the 1H sandwich structure have the three planes of 2D hexagonally packed atoms (X–M–X) ABA Bernal stacking; the 1T has the three atomic planes that form the ABC rhombohedral stacking, where the metal atoms are in octahedral coordination with the chalcogen atoms. This structure in free-standing form is unstable and devoted to go to a spontaneous lattice distortion (Qian et al., 2014). This lattice distortion in the x direction forms a periodic 2×1 distorted structure, the so called $1T'$, consisting of 1D zigzag W atoms chains, upset from the original octahedral positions, along the perpendicular y direction (Eda et al., 2012; Qian et al., 2014; Tang et al., 2017).

The $1T'$ structure was the issue of the work reported in Ref. (Qian et al., 2014), where it was found that an intrinsic band inversion between chalcogenide-*p* and metal-*d* bands is originated by this structural distortion, and, in addition, the SOC opens a tunable gap, both upon a vertical electric field and strain.

The case of $1T'$ -WS₂ on bilayer graphene/SiC(0001)

As a witness to the richness of the electronic properties of this class of Dirac 2D materials among the TMDs, we report one of the most significant example in quantum spin Hall state observed in monolayer $1T'$ -WTe₂ (Tang et al., 2017).

A monolayer $1T'$ -WTe₂ was epitaxially grown on bilayer graphene/ SiC(0001) and studied by ARPES and first-principles calculations, providing the signature of the topological band inversion and band gap opening, trademarks of the QSH state in this material (Tang et al., 2017).

Fig. 8(a) reports the $1T'$ -WTe₂ crystal structure with the 2×1 periodicity induced by the spontaneous lattice distortion from 1T phase; the unit cell is indicated by the red rectangle.

The schematic panel that details the mechanism of the transition from a topologically trivial phase, ($Z_2 = 0$), to a non-trivial phase and then to a bulk band opening due to SOC ($Z_2 = 1$) for a bulk band is displayed in Fig. 8(b), whereas the calculated band structures for WTe₂, which evidence the evolution from $1T$ -WTe₂ to $1T'$ -WTe₂ without SOC, and $1T'$ -WTe₂ with SOC, along the $\bar{\Gamma} - \bar{Y}$ direction are shown in Fig. 8(c–e). Here, the red and blue dotted bands feature the two bands involved in band inversion, and the + and – signs denote the parity of the Bloch states at the $\bar{\Gamma}$ point (Tang et al., 2017).

The measured ARPES pattern, along the $\bar{Y} - \bar{\Gamma} - \bar{Y}$ direction, from $1T'$ -WTe₂, its second derivative spectrum, the band structure calculations (including the $\bar{\Gamma} - \bar{Y} - P/P'$) and the rectangular BZ are displayed in (f–i), respectively. A very nice agreement between the ARPES measurements and calculation, points to a clearly band inversion, and a large bulk band gap opening of 55 meV.

Furthermore, in addition, the STS showed the evidence of the insulating bulk and conductive edge nature of $1T'$ -WTe₂, giving the compelling experimental evidence of a QSH insulator phase in monolayer $1T'$ -WTe₂ (Tang et al., 2017).

Conclusion

This chapter has been conceived to offer an overview of the most significant works of Dirac's 2D systems, carried out in the last few years after the graphene discovery.

The richness of the specific characteristics of 2D Dirac materials beyond graphene, belonging to group-IIIA, IVA, VA, VIA, IVB, as well as the TMDs, have been considered both from a theoretical and an experimental point of view, showing their hidden features seen through the eyes of modern research.

Examples of these elemental 2D Dirac materials following a timeline for their discovery, such as silicene and multilayer silicene, showing the Dirac cone; stanene, bismuthene, as well as the $1T'$ -WS₂ TMD, exhibiting large QSH effect have been largely mentioned.

Fig. 8 1T'-WTe₂ crystal structure with the 2×1 periodicity; the units cell is indicated by the red rectangle (a); schematic panel which describes a bulk band changing from a topologically trivial phase, ($Z_2 = 0$), to a non-trivial phase and then to a bulk band opening due to SOC ($Z_2 = 1$) (b). The calculated band structures for WTe₂, which evidences the evolution from 1T-WTe₂ (c) to 1T'-WTe₂ without SOC (d), and 1T'-WTe₂ with SOC (e), along the $\bar{\Gamma}-\bar{Y}$ direction. The measured ARPES on 1T'-WTe₂, its second derivative spectrum, the band structure calculations, and the rectangular BZ are displayed in (f-i), respectively. Adapted from Fig. 1 and Fig. 2 of Tang S, Zhang C, Wong D, Pedramrazi Z, Tsai H-Z, Jia C, Moritz B, Claassen M, Ryu H, Kahn S, Jiang J, Yan H, Hashimoto M, Lu D, Moore RG, Hwang C-C, Hwang C, Hussain Z, Chen Y, Ugeda MM, Liu Z, Xie X, Devereaux TP, Crommie MF, Mo S-K, and Shen Z-X (2017). Quantum spin Hall state in monolayer 1T'-WTe₂. *Nature Physics* 13: 683–687.

All these excellent reported cases have marked a paradigm, capable to stimulate a remarkable way to design new Dirac 2D monolayer and/or monolayer-substrate composites with large QSH gap and conductive spin-protected TDBSs, as well as unexpected physical properties, under appropriate materials engineering, which could be applied in a near future.

Definitely, quantum spin Hall Dirac materials could hold the promise of having revolutionary devices with dissipationless spin current, with opportune large gap, operating at high temperature. Strain engineering, surface epitaxy, both flat and buckled 2D system, in conjunction with outstanding insights and physical apparatus, can highlight the importance of the elemental adlayer-substrate in obtaining artificial 2D Dirac materials, for exploring new condensed matter physical properties.

In addition, the TMDs QSH insulator should provide new opportunities for both fundamental studies and novel device applications.

In conclusion, the 2D artificial elemental materials with the suffix-ene that came after the progenitor graphene first, and successively silicene, known as Xenos, have been enormously attracted the attention of the scientific research world both from experimental and theoretical point of view. Furthermore, the hint for new 2D silicon/stanene/plumbene systems for superconductivity purpose, will pushes the research toward the epitaxial growth through the formation of a substrate-metal-silicon interface.

Abstract

In Westminster Abbey, in a nave near to Newton's monument, lies a memorial stone to Paul Dirac. The inscription on the stone includes the relativistic wave equation for an electron: the Dirac equation. At the turn of the 21st century, it was discovered that this eponymous equation was not simply the preserve of particle physics. The isolation of graphene by Andre Geim and Konstantin Novoselov in Manchester led to the exploration of a novel class of materials—Dirac materials—whose electrons behave like Dirac particles. While the mobility of these quasi-relativistic electrons is attractive from the perspective of potential ultrafast devices, it also presents a distinct challenge: how to confine Dirac particles so as to avoid making inherently leaky devices? Here we discuss the unconventional quantum tunneling of Dirac particles, we explain a strategy to create bound states electrostatically, and we briefly review some pioneering experiments seeking to trap Dirac electrons.

Key points

- The Dirac equation has utility in condensed matter physics, where it can describe the electrons in materials such as graphene.
- Confinement in Dirac materials is notoriously difficult due to the Klein paradox (which arises during quantum tunneling of quasi-relativistic particles).
- Unexpectedly, bound states may form at the Dirac point (that is, at the apex of the cone formed in the electron energy-momentum relation of quasi-relativistic particles).
- Recent experiments have measured the signatures of confinement in electrostatically defined graphene quantum dots.

Introduction

Friday nights in the laboratory of Andre Geim and Konstantin Novoselov at the University of Manchester were routinely set aside for more playful work. One such speculative idea was to rip layers of carbon from a lump of graphite using sticky tape (Novoselov, 2011; Geim, 2011). Remarkably, they were able to isolate a single atomic layer of graphite: graphene. Just a few years later in 2010, they were jointly awarded the Nobel Prize in physics for their discovery of (and groundbreaking experiments with) graphene, whose atoms are arranged in a purely two-dimensional honeycomb array resembling chicken wire (Castro Neto et al., 2009; Abergel et al., 2010; Peres et al., 2010; Das Sarma et al., 2011).

Of all of the many wonderful properties of the 2-D material graphene, perhaps the most interesting stem from its link to particle physics (Katsnelson, 2012). Near to the Fermi level the electron band structure in graphene is linear,

$$E_{\pm} = \pm v_F |p|, \quad (1)$$

suggesting its electrons and holes, of momentum p , are massless particles which travel with some constant speed v_F (in some sense, an effective speed-of-light for the material). Furthermore, the Hamiltonian describing these charge carriers formally maps onto a massless, two-dimensional Dirac equation such that a treasure trove of quasi-relativistic phenomena arise in a humble pencil trace of graphite (Shen, 2012; Thaller, 2013). Some examples of such phenomena include Klein tunneling, atomic collapse, and Lorentz boosts (Chen et al., 2007; Shytov et al., 2007; Shytov et al., 2009).

Explicitly, the single electron Hamiltonian $\hat{H}$ describing massless Dirac fermions in two-dimensions $r = (x, y)$ reads

$$\hat{H} = v_F \boldsymbol{\sigma} \cdot \hat{\mathbf{p}} + V(r), \quad (2)$$

where v_F is the Fermi velocity of the Dirac material, the two-dimensional momentum operators are $\hat{p} = (\hat{p}_x, \hat{p}_y)$, $\sigma = (\sigma_x, \sigma_y, \sigma_z)$ are Pauli's spin matrices and $V(r)$ is a scalar confinement potential. Importantly, the 2×2 matrix Hamiltonian $\hat{H}$ of Eq. (2) must act on a two-component spinor wavefunction Ψ , where

$$\Psi(r) = \begin{pmatrix} \psi_A(r) \\ \psi_B(r) \end{pmatrix}, \quad (3)$$

which in the case of graphene has arisen from the two interlocking triangular sublattices A and B , together creating the overall honeycomb lattice.

Klein tunneling

The spinor wavefunction of graphene gives rise to the concept of pseudospin (Beenakker, 2008), which is encapsulated by the relation $\sigma \cdot \hat{p}/|p| = \pm 1$. This neat equations shows that the direction of the charge carrier motion is pinned: for electrons $\sigma \cdot \hat{p}/|p| = \pm 1$ and for holes $\sigma \cdot \hat{p}/|p| = -1$. As such, it is difficult to backscatter massless Dirac particles, which makes them highly desirable for electronic devices requiring significant mobilities.

In nonrelativistic quantum mechanics, a particle impinging upon a one-dimensional potential barrier can tunnel pass through the obstacle despite classical physics suggesting it would be reflected. Nevertheless, the transmission probability decreases exponentially with increasing barrier height. However, in relativistic quantum mechanics an even more counter intuitive phenomena can occur. When a relativistic particle meets a large potential barrier it may pass through perfectly, that is with a transmission probability of one (Allain and Fuchs, 2011). This effect is known as Klein tunneling, and it can be understood as arising due to the conservation of pseudospin (Katsnelson et al., 2006). An electron moving to the right becomes a right-moving hole under the high potential barrier and an electron again outside of the barrier, always ensuring $\sigma \cdot \hat{p}/|p| = 1$ throughout the propagation, such that the particle continues its rightwards journey. Clearly, confining massless Dirac particles electro-statically in one dimension presents a nontrivial task due to this tunneling phenomenon.

Confinement in two-dimensions

The Hamiltonian $\hat{H}$ of Eq. (2) acts upon a spinor wavefunction Ψ , which has two-components as shown in Eq. (3). When considering radially symmetric problems, such that the scalar potential $V(r) = V(r)$, the wavefunction Ψ in radial coordinates (r, θ) has the separable form

$$\Psi(r, \theta) = \frac{e^{im\theta}}{\sqrt{2\pi}} \begin{pmatrix} \chi_A(r) \\ ie^{i\theta} \chi_B(r) \end{pmatrix}, \quad (4)$$

where the two radial functions $\chi_A(r)$ and $\chi_B(r)$ are to be found, and the prefactor $1/\sqrt{2\pi}$ normalizes the angular part of the wavefunction. The integer quantum number $m = 0, \pm 1, \pm 2, \dots$ arises from a consideration of the total angular momentum quantum number j_z , where

$$j_z = m + 1/2. \quad (5)$$

Explicitly, the spinor wavefunction of Eq. (4) satisfies the eigenvalue equation $\hat{J}_z \Psi = j_z \Psi$, where the angular momentum operator $\hat{J}_z$ reads

$$\hat{J}_z = -i\partial_\theta + \sigma_z/2. \quad (6)$$

The wavefunction Ψ given by Eq. (4) can then be seen to separate the two spatial variables in the Schrödinger equation

$$\hat{H}\Psi(r, \theta) = E\Psi(r, \theta), \quad (7)$$

so that, after using the momentum component relations $\hat{p}_x = -i\hbar\partial_x$ and $\hat{p}_y = -i\hbar\partial_y$, as well as the Cartesian to polar coordinate partial derivatives

$$\partial_x = \cos\theta\partial_r - \frac{\sin\theta}{r}\partial_\theta, \quad \partial_y = \sin\theta\partial_r + \frac{\cos\theta}{r}\partial_\theta, \quad (8)$$

one arrives at a pair of coupled first-order differential equations for the two radial components $\chi_A(r)$ and $\chi_B(r)$,

$$\left(\partial_r + \frac{m+1}{r}\right)\chi_B = [\varepsilon - U(r)]\chi_A, \quad (9a)$$

$$\left(-\partial_r + \frac{m}{r}\right)\chi_A = [\varepsilon - U(r)]\chi_B. \quad (9b)$$

Here the scaled eigenvalue $\varepsilon = E/\hbar v_F$, and the scaled potential function $U(r) = V(r)/\hbar v_F$, absorb the dependence on the Fermi velocity v_F .

A second-order differential equation for the upper component of the radial wavefunction $\chi_A(r)$ only can be computed by disentangling the system of two equations given by Eqs. (9a) and (9b) resulting in

$$\chi_A'' + \left(\frac{1}{r} + \frac{U'}{\varepsilon - U}\right)\chi_A' + \left([\varepsilon - U]^2 - \frac{m^2}{r^2} - \frac{m}{r} \frac{U'}{\varepsilon - U}\right)\chi_A = 0. \quad (10)$$

Here the notation ' and '' denotes taking one or two derivatives of the function with respect to r . A corresponding equation for the lower radial wavefunction component $\chi_B(r)$ may be obtained upon making the replacements $A \rightarrow B$ and $m \rightarrow -(m+1)$ in Eq. (10), as follows from Eqs. (9a) and (9b).

Importantly, a consideration of any fast-decaying function $U(r)$ allows one to neglect all terms involving both U and U' in Eq. (10), such that the equation essentially becomes Bessel's differential equation. The two linearly independent solutions, being Bessel functions of the first and second kinds, are standard scattering solutions and so one is lead to conclude bound states are seemingly not possible, as was pointed out by Tudorovskiy and Chaplik (Tudorovskiy and Chaplik, 2007). However, this argument implicitly assumes the states considered have a nonzero energy, such that $\varepsilon \neq 0$ always in Eq. (10). If one allows for zero energy states ($\varepsilon = 0$) then Eq. (10) no longer maps onto Bessel's differential equation, opening up an opportunity for bound states with electrostatic confining potentials to plausibly emerge (Bardarson et al., 2009).

Maxwell's fish-eye lens and bound states

Let us try to construct zero energy ($\varepsilon = 0$) solutions of the massless Dirac equation, associated with the Hamiltonian of Eq. (2). Inspired by the Lorentzian function exploited by Maxwell for his fish-eye lens (Niven, 1890), we shall choose the smooth confining potential (Downing et al., 2011; Downing and Portnoi, 2017)

$$V(r) = \frac{-V_0}{1 + r^2/d^2}, \quad (11)$$

where the potential strength is V_0 , while d measures the spatial extent of the potential. Remarkably, this bell-shaped function allows for an exact solution of Eq. (7).

One may solve the coupled Eqs. (9a) and (9b) by initially finding just the upper radial wavefunction component $\chi_A(r)$. A short-range analysis of Eq. (10) suggests that at $r \rightarrow 0$ the solution should be of the form

$$\chi_A \sim r^{|m|}, \quad (12)$$

where the alternative solution $\chi_A \sim r^{-|m|}$ is discarded due to its divergence at the origin, as is familiar from non-relativistic central potential problems. A similar long-range analysis as $r \rightarrow \infty$ suggests the proper solution should decay like

$$\chi_A \sim \frac{1}{r^2 p_m - |m|}. \quad (13)$$

In the above equation, we have introduced the m -dependent parameter p_m , defined as

$$p_m = \frac{1}{2}(1 + |m| + |1 + m|). \quad (14)$$

For later convenience, if we switch to a new variable ξ , where

$$\xi = (r/d)^2, \quad (15)$$

an appropriate ansatz solution of Eq. (10), which accounts for both the short-range and long-range behaviors as encapsulated by Eqs. (12) and (13) respectively, is

$$\chi_A = \frac{C}{d} \frac{\xi^{\frac{|m|}{2}}}{(1 + \xi)^{p_m}} w(\xi), \quad (16)$$

where we have introduced the dimensionless number C as a normalization constant for the radial part of the wavefunction, which ensures that

$$\int_0^\infty (|\chi_A|^2 + |\chi_B|^2) r dr = 1. \quad (17)$$

In Eq. (16), $w(\xi)$ is an unknown function which has no influence on the small or large asymptotics of the overall upper radial wavefunction component χ_A . Upon substituting Eq. (16) into Eq. (10), we find the following second-order differential equation determining the as yet unspecified function $w(\xi)$

$$\begin{aligned}
& \xi(1+\xi)^2 w''(\xi) \\
& + (1+\xi)[1+|m|+(2+|m|-2p_m)\xi]w'(\xi) \\
& + \left[\left(\frac{V_0 d}{2\hbar v_F} \right)^2 - p_m^2 \right] w(\xi) = 0.
\end{aligned} \tag{18}$$

The solution of Eq. (18) can be given in terms of the Gauss hypergeometric function ${}_2F_1(a, b; c; z)$, which has the power series definition

$${}_2F_1(a, b; c; z) = 1 + \frac{ab}{c} \frac{z}{1!} + \frac{a(a+1)b(b+1)}{c(c+1)} \frac{z^2}{2!} + \dots \tag{19}$$

One finds the explicit form of the solution of Eq. (18) as

$$w(\xi) = {}_2F_1\left(p_m + \frac{V_0 d}{2\hbar v_F}, p_m - \frac{V_0 d}{2\hbar v_F}; 1 + |m|; \frac{\xi}{1+\xi}\right), \tag{20}$$

while the precise structure of χ_B is now readily obtained from Eq. (9b) since χ_A has been found.

It is implicit that the infinite power series inside Eq. (20) must be terminated, so that χ_A satisfies the required conditions on its limiting behavior, as determined at the outset by Eq. (12) and Eq. (13). Given this termination, the radial asymptotics of the radial component wavefunctions are

$$\lim_{r \rightarrow \infty} \begin{pmatrix} \chi_A \\ \chi_B \end{pmatrix} \propto \begin{pmatrix} 1/r^{1+|1+m|} \\ 1/r^{1+|m|} \end{pmatrix}, \tag{21}$$

which suggests that the presence of algebraically decaying, but marginally non-square-integrable, extended states with quantum numbers $m = \{0, -1\}$, and otherwise genuine, fully square-integrable bound states with $m \neq \{0, -1\}$. Some typical bound states are plotted in Fig. 1.

The quantization condition for zero energy ($\varepsilon = 0$ or equivalently $E = 0$) bound states arises by assigning the second argument in the hypergeometric function of Eq. (20) to be a non-positive integer n , thus terminating the power series and leading to the bound state conditions

$$\frac{V_0 d}{\hbar v_F} = 2(n + p_m), \quad E = 0, \tag{22}$$

where $n = 0, 1, 2, \dots$, and the m -dependent parameter p_m is defined in Eq. (14). All of the modes of Eq. (22) appear at even integer values of the dimensionless quantity $V_0 d/\hbar v_F$, which are associated with increasingly large degeneracies. For example, at the bound state condition $V_0 d/\hbar v_F = 4$ there is a two-fold degeneracy, due to the states $(n, m) = (0, 1)$ and $(0, -2)$, and there is a four-fold degeneracy when $V_0 d/\hbar v_F = 6$, due to the states $(n, m) = (0, 2)$, $(0, -3)$, $(1, 1)$ and $(1, -2)$.

The features of this fish-eye lens model suggest some general conclusions about bound states of massless Dirac particles may be drawn. Firstly, bound states may only arise at the apex of the energy-momentum cone (the so-called Dirac point) so they are zero-energy bound states ($E=0$). Secondly, they are only supported at critical values of the dimensionless parameter arising from the potential strength and shape (in this case, $V_0 d/\hbar v_F$). Thirdly, there is a threshold value at which the first bound state appears (in our example, $V_0 d/\hbar v_F = 4$). Finally, the angular momentum quantum number m is required to be $m \geq 1$ or $m \leq -2$ for the state to be normalizable. States with $m = 0$ and $m = -1$, or equivalently from Eq. (6) with total angular momentum number $j_z = |1/2|$, are a marginal kind of extended state.

Experiments

The quest to observe bound states of massless Dirac particles in graphene and related materials started soon after the isolation of graphene by Geim and Novoselov in Manchester in 2004. Early work used methods like applying high magnetic fields or chemical engineering (Goerbig, 2011), but such techniques are arguably undesirable for future technological applications. Therefore, electrostatic confinement remained a holy grail in the early years of massless Dirac fermion research.

A breakthrough was reported in 2015 by Yue Zhao and co-workers, who were influenced by the so-called whispering gallery modes known from the closed acoustics of cathedrals (Zhao et al., 2015). The team used a scanning tunneling probe to create a circular p-n junction, and exploited the tunability of the charge carriers of graphene to engineer controllable whispering gallery mode resonators. They observed various degrees of confinement via resonances in the tunneling spectrum, where particularly strong confinement was found by carefully tuning the cavity radius using gate potentials. Therefore, this pioneering work provided a clear perspective for the creation of zero-energy bound states electrostatically.

Soon afterwards, Juwon Lee and colleagues observed bound states in graphene quantum dots in a landmark paper from 2016 (Lee et al., 2016). They fabricated circular quantum dots by careful manipulations of defect charges in the insulator substrate sitting below the monolayer of graphene. The team was able to map spatially the electronic structure inside and outside the quantum dot, providing insight into the quantum interference patterns associated with longer living states.

Fig. 1 Probability densities of bound states in a Lorentzian confining potential [cf. Eq. (22)]. Panels (a, b, c): the quantum number $n = 0, 1, 2$ respectively. In the figure, the quantum number angular momentum $m = 1$.

In the same year, Christopher Gutierrez and co-workers similarly used substrate engineering to create a circular graphene quantum dot (Gutierrez et al., 2016). They revealed long-lived states locally pinned within a larger monolayer sheet of graphene. In particular, they observed essentially bound states, at particular energies and of a certain angular momentum, which were achieved by carefully tuning the geometry of the barrier.

Taken together, these three aforementioned experimental works suggest that the creation and mastery of electrostatic confinement with massless Dirac particles, with a view toward future exploitation in nanoscopic devices, remains an important area of condensed matter physics research.

Conclusion

We have discussed how Dirac materials, such as the Nobel Prize winning wonder material graphene, allow one to explore some aspects of quantum electrodynamics in condensed matter physics thanks to their shared reliance on various forms of Dirac equation. One such example is Klein tunneling, or the perfect tunneling of massless particles normally incident on high potential barriers. This effect suggests that the creation of electrostatic quantum dots in Dirac materials is a highly nontrivial task.

We have considered theoretically a possible route to create trapping of massless particles, by considering zero energy states in electrostatic confining potentials. Via a beautiful, exactly-solvable model, inspired by Maxwell's fish-eye lens, we have described some key properties of such novel bound states arising at the Dirac point.

Finally, we have briefly reviewed some exciting experimental work on graphene quantum dots. As it stands, the complete mastery of the confinement of massless particles, a key blockage preventing the development of ultrafast, ultracompact electronics based on Dirac materials, remains fertile ground for modern condensed matter physics studies.

Abstract

Systems that can be described with the same mathematical models that account for the properties of electrons in graphene are known as graphene-like systems. These include magnons, photons, polaritons, acoustic waves, and electrons in honeycomb lattices, either natural or artificial. All of them feature an outstanding property, the existence of states localized at the edges. We distinguish two classes of edge states depending on whether or not a topological band gap is present in the two-dimensional energy bands. We introduce the theory of edge states in terms of tight-binding models and discuss their properties, with an emphasis on the interplay between their one-way character and the topological nature of the bulk phase.

Key points

- Graphene-like systems can be modeled with a tight-binding model that describes a honeycomb lattice with one state per site, resulting in peculiar energy dispersions, both in bulk, with Dirac cones, and at the edges.
- States localized at the boundaries are known as edge states.
- The properties of the edge states are intimately related to the topological properties of the bulk. When a topological gap opens in bulk, in-gap edge states exist in all boundaries. Otherwise, zero-energy edge states exist only along certain crystallographic directions.

Introduction

Main properties of graphene band structure

Graphene is a two-dimensional material made of carbons forming a honeycomb lattice. Its electronic properties are often described (Castro Neto et al., 2009) with a tight-binding model with only one atomic orbital per carbon and first-neighbor hopping. This model has three outstanding properties:

1. It has two energy bands, on the account of the two sites in the unit cell of the honeycomb lattice.
2. The two energy bands become degenerate at two points in the six corners of the hexagonal Brillouin zone.
3. In the neighborhood of these degenerate points, the energy bands form two Dirac cones with electron-hole symmetry.

*On permanent leave from Departamento de Física Aplicada, Universidad de Alicante, Spain.

In the rest of this chapter, we choose our energy origin, $E = 0$, at the degeneracy points and we refer to them as the Dirac points. The lattice shows C_3 symmetry, that remains invariant under rotations of 120 degrees. Only two groups of three equivalent corners or Dirac points are actually different states of the crystal. We refer to these groups as *valleys*, and we label them as K and K' .

Importantly, there are several physically relevant perturbations to the first-neighbor hopping tight-binding model that lead to the opening of a *gap* between the two bands. In some cases, these perturbations make graphene enter a topological phase, different from conventional insulators, having an important impact on the edge states. We shall distinguish two broad types of topological states in graphene, Chern insulators (Haldane, 1988) and Quantum Spin Hall insulators (Kane and Mele, 2005). The Quantum Hall phase promoted in graphene by the application of an external magnetic field perpendicular to the honeycomb plane (Castro Neto et al., 2009) belongs to the Chern-insulator type.

Graphene-like systems

Many of these properties, including the Dirac cones in the bulk dispersion, the topological-gap openings, are shared by a class of systems that can be described with the same mathematical models than graphene and its topological variants (Polini et al., 2013; Lado et al., 2015). The relevant degrees of freedom in these graphene-like systems are not only electrons but also magnons, photons of various wavelengths, polaritons, and sound waves. Some of these graphene-like systems are artificial arrays of various different types and length-scales: atomically-precise lattices crafted with a scanning tunneling microscope on a surface, arrays of quantum dots in silicon, millimeter size dielectric resonators arranged in a honeycomb lattice, and cm-scale acoustic resonators. The list of graphene-like systems, either topological or not, includes:

- Electrons in other 2D materials with honeycomb lattices and sp^2 , such as silicene and germanene, in and nanofabricated honeycomb lattices (Singha et al., 2011), surfaces with arrays of CO molecules (Gomes et al., 2012) and molecular crystals
- Magnons in ferromagnetic crystals where the magnetic atoms are disposed in a honeycomb lattice (Owerre, 2016) such as CrI_3 (Huang et al., 2017)
- Cold atoms trapped in tunable optical lattices with honeycomb geometry (Tarruell et al., 2012)
- Exciton polaritons in honeycomb arrays of micropillars (Jacqmin et al., 2014)
- Photons in honeycomb photonic lattices (Plotnik et al., 2013)
- Acoustic waves in honeycomb lattices of millimeter scale cylinders (Torrent and Sánchez-Dehesa, 2012; Khanikaev et al., 2015)

This list illustrates the diversity of physical systems, length-scales and degrees of freedom that can be described in terms of the same mathematical models.

Edges and edge states

Edge states can occur at the boundaries of graphene, where carbon atoms have only two carbon first neighbors, instead of three. They are localized in the direction perpendicular to the boundary and can be extended along the boundary. The boundaries of semi-infinite graphene are one-dimensional (1D) and they can host one-dimensional extended edge states. Very often, the energy of edge states is in the neighborhood of the Dirac points.

Edges in graphene-like systems are characterized by their orientation relative to the two high-symmetry directions in the honeycomb lattice, armchair, and zigzag (see Fig. 1A, C, and D). The most studied edges are parallel to one of these two directions. However, edges along arbitrary directions, known as chiral edges, can be considered (see Fig. 1F)

We distinguish two types of edge states, depending on whether or not graphene has a topological gap. For gapless graphene, edge states only occur for edges in a range of orientations. For instance, zigzag edges host edge states, whereas armchair do not. In gapless graphene, edge states have strictly $E = 0$ energy forming flat 1D bands (Nakada et al., 1996).

In the presence of a topological gap in the bands of 2D crystal, all boundaries of graphene do host edge states, and they have dispersive energy bands $E(k)$. For Quantum Spin Hall insulators, edge states have spin-momentum locking: at a given edge electrons with opposite spin projection along the off-plane direction propagate in opposite directions (Kane and Mele, 2005). Thus, back-scattering entails a spin-flip. In the case of Quantum Hall and Chern insulators, all edge states are chiral: propagation only occurs in one direction, regardless of the spin, making back-scattering strictly forbidden (Haldane, 1988; Lado et al., 2015).

Theory of quantum states in 2D honeycomb lattices

Graphene-like states in two dimensions

The honeycomb lattice of 2D graphene can be treated as two interpenetrating triangular lattices that we label as A and B in Fig. 1A. Thus, the honeycomb lattice is a triangular lattice with two atoms per unit cell that naturally leads, within the simple TB model, to this 2×2 Bloch Hamiltonian (Castro Neto et al., 2009):

$$\mathcal{H}_0(\vec{k}) = t \begin{pmatrix} 0 & f(\vec{k}) \\ f^*(\vec{k}) & 0 \end{pmatrix} \quad (1)$$

Fig. 1 (A) Honeycomb lattice, with the two triangular sublattices, A and B , are displayed with fake color, *red* and *blue*. (B) Brillouin zone associated to the honeycomb lattice, including the plot of the two energy bands forming Dirac cones in the neighborhood of K and K' points (see text). Four types of edges, zigzag (C), armchair (D), bearded (E), and chiral (F).

where t is the first neighbor hopping and $f(\vec{k}) = 1 + e^{i\vec{k} \cdot \vec{a}_1} + e^{i\vec{k} \cdot \vec{a}_2}$ is the Bloch hopping associated to first neighbor hopping in the honeycomb lattice, and

$$\begin{aligned}\vec{a}_1 &= \frac{a}{2} (\sqrt{3}, 1) = a(\cos 30^\circ, \sin 30^\circ) \\ \vec{a}_2 &= \frac{a}{2} (\sqrt{3}, -1) = a(\cos 30^\circ, -\sin 30^\circ)\end{aligned}\quad (2)$$

where a is the unit cell spacing, which coincides with the second neighbor distance and it satisfies the relation $a = \sqrt{3}a_{CC}$ with the first neighbor distance. The resulting energy bands, $\varepsilon_{\pm}(\vec{k}) = \pm |t| \sqrt{|f(\vec{k})|^2}$, are shown at low energies in Fig. 1B. The function $f(\vec{k})$ vanishes at the K and K' points so that the two bands meet at those points, with energy $\varepsilon = 0$. Due to the bipartite character of the honeycomb lattice, the energy bands have the so called *electron-hole* symmetry, that is, for every state with energy $+E$, there is another with energy $-E$.

At this point, we introduce the concept of sublattice as a pseudo spin degree of freedom, with Pauli matrices σ_a , $a = x, y, z$, such that σ_z is the sublattice operator. By so doing, we can write down the Bloch Hamiltonian in terms of the Pauli matrices σ_x, σ_y :

$$\mathcal{H}_0(\vec{k}) = t \left[\text{Re}(f(\vec{k}))\sigma_x + \text{Im}(f(\vec{k}))\sigma_y \right] \quad (3)$$

The resulting Bloch states can be found to be:

$$\psi_{\vec{k}, \nu=\pm 1} = e^{i\vec{k} \cdot \vec{r}} \begin{pmatrix} 1 \\ \nu e^{i\phi(\vec{k})} \end{pmatrix} \quad (4)$$

where $\phi(\vec{k})$ is the phase of the complex number $f(\vec{k})$. Importantly, all finite-energy eigenstates of $\mathcal{H}_0$, and any other bipartite model, have an equal weight on both sublattices.

In order to describe the low-energy physics of graphene, it is enough to expand the Bloch Hamiltonian of Eq. (1) the neighborhood of the K and K' points, denoted by the label $\tau_z = \pm 1$. By so doing we obtain:

$$\mathcal{H}_0(\vec{q}) = \hbar v_F (q_x \sigma_x + \tau_z q_y \sigma_y) \quad (5)$$

where $\vec{q} \equiv \vec{k} - \vec{K}_\tau$ and $\hbar v_F = \frac{3}{2} t a_{CC}$, where a_{CC} is the first-neighbor distance in the honeycomb lattice. We thus see that, in the neighborhood of the K and K' point, the graphene tight-binding Hamiltonian of Eq. (1) can be mapped into two copies, one per valley, of a Dirac Hamiltonian. Many of the low energy properties of graphene-like systems can be understood in terms of the Dirac Hamiltonian.

Band-gap opening

We now discuss different extra perturbations in the model of Eq. (1) that, while preserving the overall structure of the graphene bands, lead to band-gap openings that may or may not be topological. We start with the simplest case of a nontopological band-gap opening induced by a sublattice symmetry breaking term, as it would happen for instance in 2D boron nitride:

$$\mathcal{H}_{BN} = \begin{pmatrix} \frac{\Delta}{2} & t f(\vec{k}) \\ t f^*(\vec{k}) & -\frac{\Delta}{2} \end{pmatrix} \quad (6)$$

It is apparent that, at the Dirac points, the off-diagonal terms vanish and the eigenvalues are $E = \pm \frac{\Delta}{2}$ so that a band gap of dimension Δ opens up at the Dirac points. Importantly, Δ is momentum independent so that it has the same sign at both valleys.

We now consider the Haldane model (Haldane, 1988) that also leads to a gap opening at the valleys, but with opposite sign. This turns out to be essential to make this gap topological. The Haldane model amounts to add to Eq. (1) a term that accounts for local magnetic fields with a vanishing total flux. These magnetic fields give rise to an imaginary second-neighbor hopping:

$$\mathcal{H}_{Haldane} = \begin{pmatrix} t_H g(\vec{k}) & t f(\vec{k}) \\ t f^*(\vec{k}) & -t_H g(\vec{k}) \end{pmatrix} \quad (7)$$

where $g(\vec{k}) = 2(\sin \phi_2 - \sin \phi_1 + \sin(\phi_1 - \phi_2))$, where $\phi_{1,2} \equiv \vec{k} \cdot \vec{a}_{1,2}$. In graphene, the magnetic field required to realize the Haldane term cannot be directly created externally on account of their very rapid space modulation. In contrast, in some graphene-like systems, the second-neighbor Haldane hopping can be engineered in the lab. For instance, in the case of magnons, second-neighbor Dzyaloshinskii–Moriya interactions give rise to Haldane-type terms in the magnon Hamiltonian (Owerre, 2016).

A kp expansion of the Haldane term around the Dirac point would yield the following extra term in the Dirac Hamiltonian:

$$\delta \mathcal{H} = \frac{3}{2} \sqrt{3} t_H \tau_z \sigma_z = \frac{\Delta}{2} \tau_z \sigma_z \quad (8)$$

so that a gap of magnitude $\Delta = 3\sqrt{3}t_H$ opens up at the Dirac point. If we define the *sign* of the gap, encoded in τ_z , the gap in the two valleys of the Haldane model has opposite signs.

This gap turns out to be topological. To see that, we define the Chern number associated to a band n as the integral over the Brillouin zone

$$C_n = \frac{1}{2\pi} \int_{BZ} \Omega_n d^2 k \quad (9)$$

where Ω_n is the Berry curvature

$$\Omega_n = i(\partial_{k_x} \langle \Psi_n | \partial_{k_y} | \Psi_n \rangle - \partial_{k_y} \langle \Psi_n | \partial_{k_x} | \Psi_n \rangle) \quad (10)$$

These expressions, valid for nondegenerate bands, can be easily generalized to the multiband case.

The Chern number can only take integer values when the integral encompasses the whole Brillouin zone. Parametric deformations of a Hamiltonian that preserve the symmetry and do not close the gap do not change the Chern number. This robustness is the key property of topological insulators. Importantly, the value of the Chern number determines the Hall conductance via the TKNN formula, $\sigma_{xy} = \frac{e^2}{h} \sum_n C_n f_n$, where $f_n = 0, 1$ marks the occupation of the band n at zero temperature. For trivial two-dimensional insulators, the Chern number vanishes, and so it does the Hall conductance. For a class of two-dimensional topological insulators, including graphene and other 2D systems in the Quantum Hall regime, the Chern number is finite and the Hall conductance is quantized. The Haldane model was the first example of a band insulator with nonvanishing Chern number and no Landau Levels. The existence of edge states in topological insulators is essential for the quantized Hall conductance.

The Chern number for the two bands of the Haldane model is (Haldane, 1988; Lado et al., 2015):

$$C_{\pm} = \pm \text{sign}(t_H) \quad (11)$$

For the Haldane model, the dominant contribution to the Chern number in Eq. (9) comes from the neighborhood of the K and K' points. We can actually compute the Berry curvature of a massive Dirac model $\mathcal{H}_0 + \delta\mathcal{H} = \hbar v_F (q_x \sigma_x + \tau_z q_y \sigma_y) + \frac{\Delta}{2} \sigma_z$ as

$$C(\Delta, \tau_z) = \frac{1}{2} \tau_z \frac{\Delta}{|\Delta|} \quad (12)$$

For the sake of the discussion we can think of the Berry curvature as a magnetic field and the Chern number as a flux. From Eq. (12) we see that in the Haldane model the sum over the two valleys leads to a $C = 1$. In contrast, when the gap is opened by the breaking of sublattice symmetry, as in Eq. (6) the total Chern number vanishes.

So far, the discussion has ignored the spin degree of freedom and all our statements hold true for each spin channel separately. Therefore, if we define a Haldane model for spinful fermions, the Chern number would be 2. In 2004, Kane and Mele (Kane and Mele, 2005) found out that the model Hamiltonian that describes graphene with intrinsic spin orbit coupling is mathematically equivalent to a *spin-dependent second-neighbor Haldane coupling*:

$$\mathcal{H}_{KM} = \begin{pmatrix} st_{KM}g(\vec{k}) & tf(\vec{k}) \\ tf^*(\vec{k}) & -st_{KM}g(\vec{k}) \end{pmatrix} \quad (13)$$

where $s = \pm 1$ labels the spin. Thus, graphene was predicted to have a gap at the Dirac point, given by $3\sqrt{3}t_{KM}$. Unlike the Haldane model, the Kane–Mele model preserves time reversal symmetry and, consequently, the total Chern number, once we sum over the spins, is zero. Therefore, the Kane–Mele model does not describe a Chern insulator. Yet, the model defines a topological insulator, different from vacuum, that is characterized by a Z_2 topological index and the emergence of spin-chiral edge states (see next section). The magnitude of the gap is predicted to be smaller than a fraction of meV, on account of the very small spin–orbit coupling of carbon. Therefore, for most practical purposes, graphene can be considered gapless. Yet, the conceptual importance of this prediction was very important, as it triggered the quest of artificial graphene realizations with this type of topological gap (Jotzu et al., 2014; Marrazzo et al., 2019, 2018).

Once spin degree of freedom is considered, there are at least two other mechanisms to turn graphene into a Chern insulator. The first mechanism, proposed by Qiao et al. (2010), combines an off-plane Zeeman splitting, induced for instance by spin proximity with a ferromagnet with off-plane easy axis, and a second type of spin–orbit interaction that arises in graphene when mirror symmetry is broken, the so called Rashba spin–orbit coupling. The Zeeman splitting of the Dirac cones leads to crossing of the electron-like band of one spin channel with the hole-like band of the other, exactly at $E = 0$, with coincides with the Fermi energy at half-filling. Rashba spin–orbit coupling mixes the two spin channels, leading to a band-gap opening at the Dirac energy, that turns out to have a finite Chern number. An alternative mechanism not relying on spin–orbit coupling consists on using exchange interaction to a magnetic skyrmion lattice placed underneath graphene (Lado and Fernández-Rossier, 2015).

Calculation methods for edge states in graphene-like systems

The calculation of edge states in graphene is not as straightforward as the calculation of bulk states on account of the reduced crystal symmetry of the problem. There are two widespread methods: (1) Computation of energy bands of 1D stripes or ribbons. (2) Green's function methods.

Energy bands of 1D stripes

We choose a crystal direction and a given width W and define a 1D crystal or ribbon with two edges. When the width of the ribbon is sufficiently large, compared to the penetration length of the edge states, the interactions between the edges are negligible, allowing to study the properties of the edge states as if they were decoupled. This method is very versatile as it permits one to include all types of terms in the Hamiltonian, including a magnetic field.

Green's function

In this approach (Lado et al., 2015), we calculate the Green's function of a semi-infinite two-dimensional crystal using the recursion method. Using the translation invariance along the direction parallel to the edge, it is possible to write the Hamiltonian of the semi-infinite crystal as a one-dimensional semi-infinite crystal whose effective Hamiltonian depends on the transverse wave vector $k_{\parallel}$. By so doing, the Green's function of the unit cell in the semi-infinite crystal reads:

$$G(k_{\parallel}, E) = (E - h_0(k_{\parallel}) - \Sigma(k_{\parallel}, E) + i\epsilon)^{-1} \quad (14)$$

where $\Sigma(k_{\parallel})$ is the self-energy induced by the coupling to the rest of the crystal:

$$\Sigma(k_{\parallel}, E) = t(k_{\parallel})G(k_{\parallel}, E)t^{\dagger}(k_{\parallel}) \quad (15)$$

where $h_0(k_{\parallel})$ and $t(k_{\parallel})$ are the intracell and intercell matrices of the Bloch Hamiltonian. Eqs. (14) and (15) define a set of nonlinear coupled matrix equations that is solved by numerical iteration. Once the surface Green's function is derived, the density of states can be obtained through $A(k_{\parallel}, E) = -\frac{1}{\pi} \text{Im}(G(k_{\parallel}, E))$. Contour plots in the $k_{\parallel}, E$ plane can reveal the existence of in-gap edge states. This method avoids the inter-edge coupling issues that may arise in the method of graphene ribbons when W is not sufficiently large.

Analytical results

We can derive edge states in the case of gapless graphene by looking for Bloch states that have imaginary momentum in the armchair direction, $\vec{k} = (i\kappa, k_y)$, and requesting they have $E = 0$. Those states would be thus evanescent in half of the plane, and itinerant along the zigzag direction. There are two ways in which we can have a state with $E = 0$: either $f(i\kappa, k_y) = 0$ and the wave function localized in sublattice A or $f^*(i\kappa, k_y) = 0$ and the wave function localized in sublattice B . These two situations lead to the following equation that relates κ and k_y is:

$$e^{\pm \frac{\sqrt{3}}{2} \kappa a} = \frac{-1}{2 \cos\left(\frac{k_y a}{2}\right)} \quad (16)$$

Since the left-hand side of this equation is positive, for real κ , we need to have $\cos\left(\frac{k_y a}{2}\right) < 1$. In addition, depending on the sign of the exponent of the left-hand side, this entails $|\cos\left(\frac{k_y a}{2}\right)|$ to be either smaller or larger than $\frac{1}{2}$. Altogether, these two conditions impose limits to the values that the transverse momentum of the edge state, k_y , can take: either in region $\frac{2\pi}{3} < |k_y a| < \pi$ or outside of this region. As we shall show right now, these two types of edge state correspond to two types of edge termination: zigzag, or the so called "bearded," both of them along the zigzag direction. In the zigzag (bearded) case, with edge states in (out of) the $\frac{2\pi}{3} < |k_y a| < \pi$ region, the density of edge states per edge atom is $1/3$ ($2/3$)

Edge states in gapless graphene

We now consider edge states in gapless graphene for zigzag edges. The prediction of Eq. (16) is confirmed by inspection of the energy bands of two very wide graphene ribbons with zigzag boundary conditions (see Fig. 2A). Most of the bands in these figures correspond to confined *bulk* (2D) states. Since the ribbons have two edges, there are two flat bands with energy $E \simeq 0$. In the case of zigzag (bearded) in the region, $\frac{2\pi}{3} < |k_y a| < \pi$. Since the extinction factor κ goes to zero for $k_y a = \pm \frac{2\pi}{3}$, there is a small hybridization of the two edge states in that region, due to the finite width of the simulation ribbon. For a given edge, inspection of the wave functions shows that wave functions are sublattice polarized at opposite sublattices for the two terminations, as expected from the analytical argument. An analogous calculation with a ribbon with armchair termination does not show edge states.

Zigzag edge states can also exist in finite size graphene systems, provided the edges are long enough. For zigzag termination, edge states occupy one-third of the Brillouin zone. Thus, there is an average of $1/3$ of edge state per edge atom. Accordingly, graphene fragments host edge states when they have zigzag edges with at least 3 edge sites. For a structure with N_A and N_B sites in the A and B sublattices, respectively, the first-neighbor TB model predicts the existence of at least $|N_A - N_B|$ zero energy states. These zero energy states, or zero modes, are sublattice polarized and very often these are localized at the edges.

Whereas the zigzag edge states occur in the absence of a topological gap in the band structure of 2D graphene, the existence of an edge state with momentum k can still be understood in terms of bulk-edge correspondence between the quantized value of the Zak phase $Z(k)$, which is a Berry phase across an appropriately chosen one-dimensional Brillouin zone (Delplace et al., 2011).

As a result of the large density of edge states at $E = 0$, which is the Fermi energy of charge-neutral graphene, zigzag edges are prone to magnetic instabilities, on account of electron-electron interactions (Yazyev, 2010). As a result, local moments are expected to exist at zigzag edges. The small magnetic anisotropy and their one-dimensional character prevent the formation of long-range magnetic order and promote quantum-disordered states instead.

Edge states in topological graphene

We now consider edge states associated to the various topological phases of graphene. There are two main differences with the edge states of gapless graphene. First, edge states occur for all edges. Second, they are dispersive. Third, for a given edge, the group velocity of edge states takes one sign only: they are *one-way states*.

We discuss three different topological phases in graphene: the Quantum Hall phase, the Chern insulator phases, and the Quantum Spin Hall phase.

Fig. 2 (A) Energy bands for zigzag ribbon in the gapless regime ($t_{KM} = t_H = \Delta = 0$). The states localized at the edges are plotted in red. (B) Wave function of the one of the $E = 0$ modes at the X point showing a strong localization in one of the edges. (C) Bands for the same system adding a sublattice imbalance term Δ in the Hamiltonian: a band gap opens in the edge states. (D) Bands for the same system with a finite value of t_H : the edge states, in red color, acquire now a dispersion. The positive and negative velocity edge states are localized at opposite edges.

Quantum Hall phase

Application of a magnetic field perpendicular to a two-dimensional electron gas (2DEG) results in the Landau quantization of the energy spectrum. Classically, electrons follow closed orbits. Quantum mechanically, electrons occupy finite size states, with a discrete energy spectrum $\varepsilon_n = \hbar\omega_0(n + \frac{1}{2})$, where $\omega_c = \frac{eB}{m}$ is the cyclotron frequency and n are integer numbers greater than 0. These are so-called Landau levels. Landau levels have a macroscopic degeneracy, associated to the location of the classical orbits across the plane. The density of such orbits, and thereby the degeneracy of the Landau levels, is determined by the magnetic field. When the density of electrons matches the density of states per Landau Level, the occupation of Landau levels at zero temperature is either complete or null: this is a Quantum Hall insulator, with the Fermi energy lying in the gap between Landau levels. Unlike normal insulator, Quantum Hall insulators have in-gap edge states and their Hall conductance is finite and quantized (Klitzing et al., 1980) in units of e^2/h . Edge states are often interpreted in terms of semiclassical skipping orbits: scattering of electrons with the edge prevents them from completing closed loops (Halperin, 1982). However, the robustness of edge states and their contribution to Quantum Hall conductance quantization lies ultimately in the topological nature of bulk states (Thouless et al., 1982), and not on the specifics of the edges.

The Quantum Hall phase picture just described holds for graphene with several differences. For Dirac electrons, instead of just one, there are two sets of Landau levels with electron-hole symmetry, one for electrons and one for holes (Castro Neto et al., 2009). Thus, for the valley $\tau = \pm 1$, there are two sets of Landau Levels $E_n = \pm \frac{\hbar\omega_0}{2} \sqrt{n + \frac{1-\tau}{2}}$ where $\omega_0 = \frac{2v_F}{\ell_B}$, $\ell_B = \sqrt{\frac{\hbar}{eB}}$, and v_F is the velocity of the Dirac electrons. In addition to these four sets of finite energy Landau levels (two per valley), there are two $E = 0$ Landau levels, one per valley.

These Landau levels, and the edge states, can be described with the same tight-binding model that describes a finite width graphene ribbon, including the effect of the magnetic field on the orbital motion of the electrons by using the Peierls substitution, where the hopping between sites α and β is replaced by:

$$t_{\alpha\beta} \rightarrow t_{\alpha\beta} e^{i\Phi_{\alpha\beta}} \quad (17)$$

where $\Phi_{\alpha\beta} = \int_{\vec{r}_\alpha}^{\vec{r}_\beta} \vec{A} \cdot d\vec{r}$ is the Peierls phase of the vector potential $\vec{A}$ associated to the magnetic field $\vec{B} = \vec{\nabla} \times \vec{A}$. For a constant magnetic field, we can choose the vector potential as $\vec{A} = B(-y, 0, 0)$ so that translational invariance is broken along the y direction,

taken to be perpendicular to the boundaries of the ribbon. Therefore, the energy states can be classified in one-dimensional energy bands.

In Fig. 4 we show the bands of graphene ribbons with armchair, zigzag, bearded, and chiral terminations. All bands have two regions, a dispersionless region that corresponds to Landau Levels, localized away from the edges, and a dispersive region associated to edge states. The calculation shows that finite energy levels have a twofold degeneracy, broken at the edges, associated to the valley degree of freedom. In contrast, the $E = 0$ LL is formed of a duet of nondegenerate electron-type and a hole-type Landau level. In the figure we also show how that dispersive states correspond to edge states and their velocity is opposite for opposite edges.

Both for the 2DEG and for graphene, the Quantum Hall conductance is given by the TKNN formula (Thouless et al., 1982) so that it is apparent the ultimate origin of its quantization is the topological nature of the band gap.

Edge states in the Chern insulator and QSH phases

We now discuss the properties of the edge states of the Chern insulating phase, as described by the Haldane model, and the Quantum Spin Hall (QSH) phase, as described by the Kane and Mele model. In both cases, there are dispersive in-gap edge states, regardless of their crystal orientation (see Figs. 2D, 3, and 5C for the Haldane model, and Fig. 5D, all of them for armchair edges). In the case of Fig. 5 we show the local-density of states, computed with the Green's function method, resolved in transverse-momentum, at the armchair boundary of a semi-infinite honeycomb lattice for three models: gapless graphene (panel 5B), Haldane model (panel 5C), and Kane–Mele model (panel 5D). At a given edge, the sign of the slope of the in-gap edge state in the Haldane model is given by the sign of t_H . Since the Kane–Mele model is equivalent to two copies of the Haldane model where the sign of the coupling is given by the spin projection along the off-plane direction, it is immediately apparent that each edge hosts two edge states, one per spin channel, with opposite velocities. This is clearly seen in Fig. 5D, obtained for a single edge using the Green's function method.

A graphical summary of the different types of edge states is shown in Fig. 6. For the topologically equivalent Quantum Hall and Chern insulating phases, the edge states circulate around the sample with sense of rotation dictated by the term in the Hamiltonian

Fig. 3 (A) Snapshot of the unit cell to generate the graphene ribbon, with the edge atoms marked in red. (B) Energy bands for armchair ribbon in the gapless regime ($t_{KM} = t_H = \Delta = 0$). The ribbon has a gaped spectrum and no edge states. (C) Bands for the same system, with a finite value of t_H ; two dispersive edge states, in red color, appear in the gap. This supports the statement that topological edge states appear in all boundaries regardless of their geometry.

Fig. 4 Energy levels for armchair (A) zigzag (B) bearded (C) and chiral (D) graphene ribbons under the influence of a magnetic field B applied perpendicular to the ribbon. For the sake of clarity, spin effects are not included in the calculation. Two types of states are shown. Dispersive edge states in *red* and dispersionless states in *black*, corresponding to Landau levels localized away from the edges. In addition, for the zigzag case, there are $E = 0$ flat edge states that were already present for $B = 0$. In the zigzag, bearded, and chiral geometry, the presence of two sets of Landau levels, corresponding to the two valleys, is apparent. In the armchair geometry, the valley degeneracy manifested as a twofold degeneracy of the Landau Levels.

Fig. 5 Schematic of the Green's function method for an armchair edge (A), and edge spectral function for a gapless armchair edge (B), with Haldane coupling (C), and with Kane-Mele coupling (D).

Fig. 6 Schematic of quantum Hall edge states (A), quantum spin Hall edge states (B), quantum anomalous Hall edge states (C) and zigzag edge states (D).

that breaks time reversal symmetry, either the external magnetic field in the Quantum Hall case or the Haldane term in the Haldane model. Edge states for these two phases cannot undergo intra-edge elastic backscattering as there are no states with opposite momentum and the same energy available. This can be connected both with the perfect quantization of their Hall conductance and their longitudinal conductance. In the case of the Kane–Mele model the edge states feature counter-propagating states with opposite spin projections. Therefore, elastic backscattering is permitted in the presence of spin-flip perturbations and not permitted if time-reversal symmetry is preserved.

Importance of edge states

Edge states have attracted interest for several reasons. In the case of nondispersive edge states, it is expected that Coulomb repulsion will promote the emergence of local moments, on account of the flat bands at the Fermi energy. There is a large body of research papers, mostly theoretical, devoted to the study of magnetism in zigzag edge states in graphene. Intra-edge interactions are expected to be ferromagnetic, at least when interactions are short-ranged (Hubbard type). However, long-range ferromagnetic order in spin-isotropic systems is not stable in 1D, on account of quantum and thermal fluctuations. Therefore, zigzag edges are expected to host fluctuating local moments, and behave as paramagnets with an enhanced spin susceptibility.

Dispersive edge states feature by the topological phases attract also enormous interest. The notion of *one way* states is of course very appealing, not only for electrons but also for other excitations. For instance, the prediction of topological magnons in 2D ferromagnetic materials with honeycomb lattices implies the existence of in-gap *one way* magnon states that may find some application in magnonbased spintronics. The perfect quantization of Hall conductance of the Quantum Hall phase is used to define the standard of the Von Klitzing constant (Klitzing et al., 1980), h/e^2 . A holy grail in quantum materials is the quest of a Chern insulator that features quantized Hall conductance without an external magnetic field.

Conclusion

We have presented the concept of graphene-like systems and we have discussed their edge states. We have stressed the interplay between the existence, or else, of a topological gap in the energy bands of the two-dimensional honeycomb system and the properties of the edge states. Specifically, for the nontopological gapless graphene phase, edge states exist only along some crystallographic directions, most notably the zigzag direction and they form flat bands, prone to magnetic instabilities. In contrast, for topological phases, edge states exist in all edges, regardless of crystallographic orientation, and they have a finite velocity and topological protection against back-scattering.

Abstract

We review the main methods used to study spin glasses. In the first part, we focus on methods for fully connected models and systems defined on a tree. These include the replica method, the Thouless-Anderson-Palmer formalism, the cavity method, and the dynamical mean-field theory. In the second part, we deal with the description of low-dimensional systems, mostly in three spatial dimensions, which are mostly studied through numerical simulations. We conclude by mentioning some of the main open problems in the field.

Key points

- An introduction to spin glasses and how they are modeled
- Analytical methods for the study of spin glasses
- Numerical results on the nature of the spin glass phase in low dimensions
- Perspectives and interdisciplinary applications.

Introduction

Spin glasses (SGs) are paradigmatic complex systems, for which disorder plays a central role. Although the term was originally coined to describe certain magnetic materials that exhibit an exotic phase behavior, associated models and theory have since found applications in a wide variety of fields, thus making the study of SGs an intrinsically interdisciplinary endeavor.

Here, we provide an overview of SGs, from their experimental context to their common theoretical models. We notably present several theoretical methods developed within the context of their study, describe the differences between mean-field and three-dimensional SGs, discuss various interdisciplinary applications, and introduce some open questions in the field.

Experimental SGs

As materials, SGs are disordered magnetic alloys containing strongly interacting ions immersed in a weakly interacting substrate. They are prepared by rapidly cooling the liquid alloy, thus fixing the strongly interacting particles at random positions within the resulting solid. The pairwise exchange interaction between ions is then positive or negative, depending on the distance vector $\mathbf{r}$ between ions, such as they are for Ruderman–Kittel–Kazuya–Yosida (RKKY) interactions,

$$J(\mathbf{r}) \sim \frac{1}{|\mathbf{r}|^3} \cos(\mathbf{k} \cdot \mathbf{r}), \quad (1)$$

where the modulus of the frequency $\mathbf{k}$ is of the order of the Fermi vector. SGs also arise in systems with interactions different from RKKY. The general idea is that because ion positions depend on the specific realization of the alloy, distances between them are randomly distributed (and a priori unknown), and therefore values of $J(\mathbf{r})$ are randomly positive and negative.

To make these systems more physically tractable, we can define SG models assuming that the distances between ions are fixed (e.g., on a lattice), and that the coupling between two ions—commonly called spins—is a quenched random variable. *Quenched* variables here refer to random quantities that appear in the Hamiltonian as parameters that do not change during the evolution of the system so as to capture that ions' positions are fixed over the relevant experimental time scales. This formulation leads to the generic SG Hamiltonian

$$\mathcal{H} = - \sum_{i < j}^N s_i \cdot J_{ij} s_j, \quad (2)$$

where the N dynamical variables are spins s_i coupled through pairwise interactions of quenched magnitude J_{ij} . Spins can be formulated in different ways, but in this section we restrict our consideration to Ising spins, $s_i = \pm 1$, both because of their simplicity and because experimental systems are typically spatially anisotropic, thus rendering effective interactions Ising-like. The quenched random variables are extracted from a distribution $P(J_{ij})$, which has support on both positive and negative values. In fully connected models, all couplings are extracted from $P(J_{ij})$ while in other models, some of the couplings are set to zero. For example, the Edwards–Anderson model (EAM) is defined by Hamiltonian (2) on a d -dimensional square lattice, so if s_i and s_j are not nearest neighbors, then J_{ij} is suppressed.

Although Eq. (2) is not the only way to model SGs (e.g., interactions can be more than pairwise), two of its features are nevertheless generic: quenched disorder and frustration. Frustration here refers to the impossibility to satisfy simultaneously all local constraints, which follows from the couplings being independent identically distributed (i.i.d.) variables that can be both positive and negative. As illustrated in Fig. 1, along a loop local coupling cannot all be minimized.

Self-averaging

Because of the quenched disorder, every SG Hamiltonian is different from all others. In other words, every *sample* corresponds to a different set of couplings J_{ij} . Interestingly, even though samples are microscopically different, experimental SG realizations display the same macroscopic behavior. SG descriptions thus work under the assumption, which holds in most relevant cases, that large SG

Fig. 1 Disordered interactions result in frustration. The signs along the edges indicate whether two neighboring spins prefer to point in the same (+) or opposite (−) directions. It is therefore impossible to satisfy all the couplings simultaneously on the square plaquette.

samples display equivalent average behavior. Therefore, although a *quenched partition function*, Z_j , can be computed for each sample, the quantity of physical interest is the *quenched free energy* averaged $(\dots)$ over the couplings distribution,

$$\mathcal{F} = \overline{\mathcal{F}}_j = -T \overline{\log Z_j}, \quad (3)$$

for Boltzmann constant set to unity $k_B = 1$, temperature T .

Order parameter

The SG order parameter is also an important matter. In a ferromagnetic system, magnetization, $M = \frac{1}{N} \langle \sum_i s_i \rangle$, distinguishes between the ferromagnetic and the paramagnetic phases. However, for the Hamiltonian in Eq. (2)—if $P(J_{ij})$ is symmetric around zero—the magnetization is zero for all temperatures.

If a low-temperature SG phase exists, there must nevertheless be some configurations that are preferred over others. One way of identifying these preferred configurations is through the *Edwards–Anderson overlap*,

$$q_{EA} = \frac{1}{N} \lim_{t \rightarrow \infty} \sum_{i=1}^N \langle s_i(0) s_i(t) \rangle_t, \quad (4)$$

where $\langle (\dots) \rangle_t \equiv \frac{1}{t} \int_0^t (\dots) dt$ marks a time average. If spins s_i have no preferred value, as in the paramagnetic phase, then the products in Eq. (4) vanish on average, and $q_{EA} = 0$; but if some configurations are preferred, each spin has a preferential value, and $q_{EA} > 0$.

As further discussed in Section “The replica method,” the overlap can also be expressed without resorting to time averages, through the concept of replicas. Replicas of a system have exactly the same couplings J_{ij} but evolve independently. For $s_i^{(a)}$ and $s_i^{(b)}$ denoting spins that belong to replicas a and b of the same sample, we can then write the overlap as

$$q_{ab} = \frac{1}{N} \sum_{i=1}^N \langle s_i^{(a)} \cdot s_i^{(b)} \rangle. \quad (5)$$

As above, the overlap will be zero if there is no preferred configuration, and positive otherwise.

Analytical methods for spin glasses

Some of the most successful methods for studying SG Hamiltonians were developed to describe fully connected models as well as models defined on tree-like graphs. The first geometry corresponds to the mean-field (MF) approximation, which becomes exact in the limit of $d \rightarrow \infty$ spatial dimensions while the second goes beyond the MF description but neglects contributions from feedback loops.

The replica method

At variance with the partition function, which is typically nonself-averaging, the free energy is key to probing the low-temperature behavior of SGs (as shown in Eq. 3). However, calculating the average of the logarithm in Eq. (3) can be challenging. The *replica method* overcomes this difficulty by replacing the calculation of $\overline{\ln Z}$ with that of $\overline{Z^n}$ through the identity

$$\overline{\ln Z} = \lim_{n \rightarrow 0} \frac{\overline{Z^n} - 1}{n}, \quad (6)$$

and by treating Z^n as the partition function for n replicas of the same sample. Treating the index n as an integer, however, hinges on the assumption that the analytical continuation $n \rightarrow 0$ exists. Assuming it does, the replicated partition function can then be rewritten as a function of the overlap matrix Q_{ab} describing the overlap between two replicas a and b :

$$\overline{Z^n} = \int \prod_{(ab)} \frac{dQ_{ab}}{2\pi} e^{N\mathcal{A}[Q_{ab}]}. \quad (7)$$

Taking advantage of the thermodynamic limit $N \rightarrow \infty$, the above expression can be evaluated by the Laplace method of saddle-point approximation, which extremizes the action $\mathcal{A}$ with respect to the reference order parameter. The final result, therefore, depends on the structure of Q_{ab} .

The simplest and most intuitive ansatz for that structure is the replica symmetric (RS) one. In this case, the overlap among different replicas is the same for any pair of replicas, with the exception of the overlap between a replica and itself. In the RS scenario, the matrix Q_{ab} therefore admits only two values: a diagonal contribution q_d (for $a = b$) and an off-diagonal one q_0 (for $a \neq b$).

Fig. 2 1-RSB parametrization of the Parisi overlap matrix. q_1 represents the degree of similarity between two replicas inside the innermost block of size $m \times m$, whereas q_0 is the outermost block value.

As expected, the RS ansatz correctly describes the high temperature and large external magnetic field regimes. But as these control parameters are lowered, some models reach a critical de Almeida-Thouless (dAT) line, below which the RS solution becomes unstable. Physically, a *spin glass* phase emerges when the RS solution is no longer stable.

More technically, below the dAT line, the correct solution requires a matrix Q_{ab} with an iterative block structure, which breaks the symmetry between different pairs of replicas. For the first iteration of replica symmetry breaking (noted 1-RSB), the $n \times n$ matrix is parametrized by a diagonal value q_d and two off-diagonal values that can be either q_1 , if the two replicas belong to the same block of size $m \times m$, or q_0 , if the replicas fall outside the innermost block (see Fig. 2). If the low-temperature phase remains unstable after 1-RSB, this procedure can be iterated within each of these blocks, leading to a k -step RSB (or k -RSB). Depending on the specifics of the Hamiltonian, SG phases can have different levels of RSB. The limit $k \rightarrow \infty$ corresponds to the full-RSB scenario, according to which the overlap matrix is parametrized by a continuous function $q(x)$, with $x \in [0, 1]$. The overlap density distribution, $P(q)$, being nonzero over a continuous range of q , is a signature of the presence of an infinite number of symmetry-breaking points.

In the replica formalism, all the mutual information about pairs of equilibrium configurations is encoded in the overlap, which is a measure of their mutual distance. Given the hierarchical way in which the full-RSB construction is obtained, in systems with a full-RSB phase, the states have an *ultrametric* structure, meaning that their mutual distance can be described through a taxonomic or genealogical tree.

The replica structure of two common MF spin glass models

For the sake of concreteness, let's consider two paradigmatic MF spin glass models. Both have a low-temperature SG phase, but with different levels of RSB, and therefore present different free energy minima structures.

- The **spherical p -spin** model has Hamiltonian

$$\mathcal{H} = - \sum_{i_1, \dots, i_p=1}^N J_{i_1, i_2, \dots, i_p} s_{i_1} \dots s_{i_p}, \quad (8)$$

where p indicates p -wise interactions to which each spin participates. Spins are continuous variables subject to the global constraint $\sum_{i=1}^N s_i^2 = N$, and the random couplings are extracted from a Gaussian distribution $P(J) = \exp\left(-J^2 \frac{N^{p-1}}{p!}\right)$, where the factor N^{p-1} guarantees the extensivity of the free energy in the thermodynamic limit. For $p \geq 3$, this class of mean-field systems is characterized by a 1-RSB low-temperature phase, with an emergent number of minima that grows exponentially with N , and those are separated by extensive barriers.

Small variations to this model result in significantly different physical behaviors. In particular, setting $p = 2$ results in only one single free-energy minimum (so there is no SG phase), whereas replacing the spherical with Ising spins results in the 1-RSB phase becoming unstable toward a full-RSB phase at low temperatures.

- The **Sherrington–Kirkpatrick** model (SK) has a Hamiltonian with an external uniform field h

$$\mathcal{H} = - \sum_{(ij)} J_{ij} s_i s_j - h \sum_i s_i, \quad (9)$$

where the sum runs over distinct pairs. The spins are Ising variables, $s_i = \pm 1$, and the random couplings are extracted from a Gaussian distribution $\mathcal{P} \simeq e^{-NJ_{ij}^2/(2J^2)}$ with zero mean and variance J^2/N . The low-temperature phase of this model is characterized by a hierarchical organization of energy minima, as given by the Parisi solution. The emergent number of minima is

subexponential in system size, and those are separated by subextensive barriers. The transition from single equilibrium (RS) to multiple equilibria (full-RSB) is second-order-like, with diverging correlation lengths and power-law singularities. The solution of the SK model obtained by the replica method was rigorously proven 30 years later. Even though there is no rigorous demonstration that the replica method is generally correct, it has since been proven to provide the correct result in several specific cases, and no counter-example is known.

The Thouless–Anderson–Palmer (TAP) approach

The TAP approach aims to probe complex energy and free-energy landscape properties through a perturbative high-temperature expansion (also known as *Plefka* or *Georges–Yedidia expansion*) by defining a Legendre transform $\mathcal{F}[\mathbf{m}]$ of the free energy as a function of the average magnetization $\mathbf{m}$. Such an expansion can detect the metastable states of the system, which correspond to the local minima of an appropriately defined nonconvex functional.

The underlying idea is to enforce the system to have single-site magnetization m_i by means of Lagrange multipliers $\lambda_i^{(\beta)}$ that depend on the inverse temperature β . Then, from the Legendre transform, one obtains

$$\mathcal{F}^{(\beta)}[\mathbf{m}] = \log \sum_{\mathbf{s}} e^{-\beta \mathcal{H}[\mathbf{s}] + \sum_i \lambda_i^{(\beta)} (s_i - m_i)} \quad (10)$$

given the stationarity condition $\lambda_i^{(\beta)} = -\frac{\partial \mathcal{F}^{(\beta)}[\mathbf{m}]}{\partial m_i}$. In the $\beta \rightarrow 0$ limit, spins are uncorrelated, making the computation of the first derivatives¹ of the free-energy functional with respect to β very straightforward:

$$\left. \frac{d\mathcal{F}^{(\beta)}[\mathbf{m}]}{d\beta} \right|_{\beta=0} = -\langle \mathcal{H} \rangle, \quad (11)$$

$$\left. \frac{d^2 \mathcal{F}^{(\beta)}[\mathbf{m}]}{d\beta^2} \right|_{\beta=0} = \left\langle \left[\mathcal{H}[\mathbf{s}] - \langle \mathcal{H} \rangle - \sum_i \frac{\partial \lambda_i^{(\beta)}}{\partial \beta} (s_i - m_i) \right]^2 \right\rangle. \quad (12)$$

The second derivative involves both the connected part of the Hamiltonian and the partial derivatives of the Lagrange multipliers. The TAP free energy can then be written as a second-order expansion around the $\beta = 0$ limit. For the SK model, it reads

$$\mathcal{F}_{\text{TAP}}^{\text{SK}}[\mathbf{m}] = -\frac{1}{\beta} \sum_i s_0(m_i) - \frac{1}{2} \sum_{i \neq j} J_{ij} m_i m_j - \frac{N\beta}{4} (1 - q)^2, \quad (13)$$

where the first term on the right-hand side accounts for entropic effects, the second term is average energy contribution, and the last one, the *Onsager reaction term*, represents a first correction to the MF approximation. It is also worth noting that since the couplings in the SK model are of order $1/\sqrt{N}$, $O(\beta^2)$ terms do matter in the final TAP expression. This contrasts with the purely ferromagnetic case (the fully connected Ising model), for which the couplings are of order $1/N$.

In the case of the spherical p -spin model, the TAP free energy reads

$$\mathcal{F}_{\text{TAP}}^{\text{pspin}}[\mathbf{m}] = -\frac{1}{\beta} \sum_i s_0(m_i) - \frac{1}{p!} \sum_{i_1, \dots, i_p} J_{i_1, \dots, i_p} m_{i_1} \dots m_{i_p} - \frac{\beta N}{4} [1 - p q^{p-1} + q^p (p-1)], \quad (14)$$

where, again, the last term represents the Onsager reaction term. By setting $m_i = 0$, one can immediately check that the TAP free energy is equal to $-\beta/4$, which is the free energy of the paramagnetic state.

In principle, the equilibrium probability distribution—hence the partition function—can always be decomposed into a combination of *pure states* α , with a free-energy density f_α . These pure states are entirely determined by a set of local observables, such as local magnetizations. The partition function can therefore be expressed as a sum over such states

$$Z = e^{-\beta N F} \simeq \sum_{\alpha} e^{-\beta N f_{\alpha}} = \int df \sum_{\alpha} \delta(f - f_{\alpha}) e^{-\beta N f} = \int df e^{N[\Sigma(f, \beta) - \beta f]} \simeq e^{N[\Sigma(f^*, \beta) - \beta f^*]}, \quad (15)$$

where in the last step we applied the saddle-point method. The configurational entropy Σ represents the logarithm of the total number of states. Evaluated at the states with f^* , which contribute maximally to Z , it leads to a simple temperature dependence of the TAP free energy with the identification $\partial \Sigma(f, \beta) / \partial f|_{f^*(\beta)} = \beta$.

In the p -spin model, this decomposition in pure states discloses a rich behavior in terms of the number of pure states that, at a given temperature, participate in the thermodynamic behavior of the system. At high temperatures, the free-energy density is ruled by a single state, the paramagnetic (Boltzmann-Gibbs) state. Upon lowering the temperature, one reaches a *dynamical transition* at temperature T_d , at which the emergence of an exponentially large number of clusters of pure states is accompanied by a dramatic slowing down of the dynamics. Surprisingly, the transition is not associated with any thermodynamic transition because the free

¹In the thermodynamic limit, all higher order terms but the first two can be neglected in a fully connected system.

Fig. 3 Left: Graph representation for the message $\hat{v}_{b \rightarrow j}(s_j)$, from the function node (square) to the variable node (circle). Right: corresponding part of the graph for the computation of the message $\hat{v}_{a \rightarrow j}(s_j)$, function of $v_{k \rightarrow a}(\sigma_k)$ from the variable node to the function node.

energy preserves its analyticity. The thermodynamic transition occurs at a lower temperature, T_s , known as *static* or *condensation transition*, where all different clusters of states collapse to the same state as a clear signature of vanishing configurational entropy.

Although the TAP approach was conceived as a high-temperature expansion, it can also be developed in terms of other perturbative quantities, such as a fictitious coupling associated with an effective energy cost. In this case, the Plefka-like expansion offers a playground for the definition of suitable effective high-dimensional potentials in situations where the energy is either ill-defined or trivially zero, such as in nonconvex constraint satisfiability problems.

The cavity method

The cavity method² was originally devised as a way to solve the SK model without resorting to the replica formalism, but can also be used to go beyond the MF approximation. It can notably consider correlations between spins, thanks to the fact that it is exact in systems with a loopless interaction graph—or with divergingly wide loops—such as in trees and some random graphs. In the following, we will focus on finite-connectivity graphs, $\mathcal{G} = (V, E)$, defined by V nodes and E edges. The Hamiltonian in Eq. (2) can be then rewritten as $E(\mathbf{s}) = -\sum_{(i,j) \in E} J_{ij} s_i s_j$, where i and j belong to the same edge E . The graph $\mathcal{G}$ together with the set of random couplings J_{ij} then defines a sample.

The main goal of the cavity method is to calculate the probability distribution of each spin, $P(s_j)$. The idea behind the approach is that $P(s_j)$ is determined by the local fields induced by all the neighbors of s_j , which are in turn determined by their own neighbors, and so on (Fig. 3). Because of the tree-like structure of the graph, the neighbors of s_j are mutually independent, and hence $P(s_j)$ can be factorized and determined through the incoming local fields, $\hat{v}_{a \rightarrow j}(s_j)$ (where a indicates a neighboring interaction): $P(s_j) \simeq \prod_{a \in \partial j} \hat{v}_{a \rightarrow j}(s_j)$. At the same time, the interaction a influencing s_j is defined by the marginal distribution of all the spins k in the neighborhood of a , once s_j is removed, $v_{k \rightarrow a}(s_j)$. Therefore, the cavity formalism results in a set of coupled equations for the marginal probability laws

$$\begin{cases} v_{j \rightarrow a}(s_i) \propto \prod_{b \in \partial j \setminus a} \hat{v}_{b \rightarrow j}(s_j), \\ \hat{v}_{a \rightarrow j}(s_j) \propto \sum_{\mathbf{s} \in \partial a \setminus j} \psi_a(\mathbf{s}_{\partial a}) \prod_{k \in \partial a \setminus j} v_{k \rightarrow a}(s_k), \end{cases} \quad (16)$$

where ψ_a is called *compatibility function*, which is analogous to the Boltzmann weight, and $\partial a \setminus j$ indicates the spins near a excluding j .

The resulting free energy as a function of fixed-point messages turns out to be a combination of three contributions coming from all function nodes, all variable nodes, and the edges connecting i to any possible function node (see Fig. 3). When the size of the loops is larger than the correlation length, the signals entering j are independent. In this case, if there is a unique solution for the state in j , the cavity method can recover it exactly. For instance, at the RS level, where there is only one pure state, the cavity approach is formally equivalent to the replica method. If the system is not RS, or if the loops are short, the approach needs to be refined. For example, 1-RSB cavity protocols have been developed to extract properties of the pure state decomposition and satisfiability conditions in generic optimization problems. Such 1-RSB message passing equations go by the name of *survey propagation* and have been generalized as *population dynamics algorithms*.

Beyond mean-field: Multilayer construction and loop corrections

The cavity method stops being exact in a non-tree-like topology and is indeed hindered by the presence of loops. Furthermore, because of its nonperturbative nature, any small parameter expansion used to compute corrections to mean-field theory appears to

²In computer science and artificial intelligence, the cavity method is also known as *Belief Propagation*, whereas in statistical physics, it is referred to as *Bethe-Peierls*.

be unfeasible. One can nevertheless build an M -layer model, where M copies of the original lattice are stacked on top of each other assuming the same distribution of random couplings. The idea—originally proposed in computer science by Vontobel—has been reworked recently in disordered systems based on a rewiring procedure. By inducing random permutations of the links, interlayer connections, and hence spatial loops, are automatically generated by a generalized transfer matrix formalism on uncorrelated one-dimensional chains. The perturbative computation of finite-size corrections in powers of $1/M$ notably offers a reliable formal method to study critical phenomena in finite-dimensional systems. The advantage of this tree-based approach is that it can recover phase transitions that deviate from the behavior of fully connected models and are instead more similar to the finite-dimension phenomenology. This situation arises, for instance, in the Random Field Ising Model, which is strongly affected by nonperturbative effects in low dimensions, and in the Anderson localization in the quantum realm.

Dynamical mean-field theory (DMFT)

Understanding the dynamics of SGs is one of the oldest and most challenging problems in the theory of matter. One characteristic feature of the SG dynamics is that its relaxation depends on the history of the system itself, that is, it ages. In other words, the autocorrelation between a time t and $t' > t$ does depend not only on $(t' - t)$ but also on the *age* of the system, t . An aging system relaxes extremely slowly without ever reaching an equilibrium state. During its exploration, the system wanders across states that are not the relevant ones from a thermodynamic viewpoint and whose static properties cannot be defined rigorously.

An MF solution for the dynamics in glassy systems was first suggested by Sompolinsky and Zippelius for equilibrium properties. Intriguing off-equilibrium features came emerged from a deeper investigation of specific models, for which a closed set of integro-differential equations could be solved.

For the sake of simplicity, in the following, we shall consider the overdamped Langevin dynamics of a system in contact with a thermal bath,

$$\frac{ds_i}{dt} = -\frac{\partial \mathcal{H}}{\partial s_i} + \eta_i(t) \quad (17)$$

whose behavior is captured by Gaussian white noise with zero mean and variance $\langle \eta_i(t) \eta_j(t') \rangle = 2T \delta_{ij} \delta(t - t')$. The index $i = 1, \dots, N$ runs over the total number of spins in the system. The Hamiltonian $\mathcal{H}$ typically incorporates a single-spin potential $V(s)$ plus a disordered part, which explicitly depends on the quenched disordered couplings (see e.g., Eq. 9), which need to be averaged out. The dynamical MF procedure allows to average over the couplings and coarsens the time dependence of the system as that of a single average spin $s(t)$. For the p -spin model, the resulting DMFT equation reads:

$$\dot{s}(t) = -\frac{\partial V(s(t))}{\partial s} + \frac{p(p-1)}{2} \int_0^t dt' R(t, t') C^{p-2}(t, t') s(t') + \xi(t) \quad (18)$$

where the noise $\xi(t)$ accounts for the interaction with the rest of the system and has an extra colored term, that is, $\langle \xi(t) \xi(t') \rangle = 2T \delta(t - t') + C(t, t')$.

The dynamical equation above is expressed in terms of the two-time correlation function

$$C(t, t') = \frac{1}{N} \sum_i s_i(t) s_i(t'), \quad (19)$$

and of the response function to an external pulse perturbation

$$R(t, t') = \frac{1}{N} \sum_i \left. \frac{\delta s_i(t)}{\delta h_i(t')} \right|_{h_i=0}. \quad (20)$$

In the thermodynamic limit, the above equations converge to a unique nonfluctuating solution, which is the only one allowed by causality. At equilibrium, $C(t - t')$ and $R(t - t')$ are related by the fluctuation-dissipation theorem, $R(t - t') = -\frac{1}{T} \Theta(t - t') \frac{d}{dt} C(t - t')$. While, for finite N , the correlation and response functions are expected to decay exponentially in time, this property is no longer generically true in the thermodynamic limit, as the relaxation time might diverge, thus signaling a dynamical transition (Section “The Thouless–Anderson–Palmer (TAP) approach”).

Based on the long-time limit analysis first performed in the spherical p -spin model, one can separately analyze the fast regime, in which relevant degrees of freedom rapidly equilibrate preserving time translation invariant (TTI) properties, and the slow regime, in which violations of fluctuation–dissipation relations and nonequilibrium phenomena emerge. In the large-time limit, for $t, t' \rightarrow \infty$, the correlation function can be split as $C(t, t') = C_{\text{TTI}}(t - t') + C_{\text{Aging}}(t, t')$. Depending on the appearance of either a single diverging timescale or a multiplicity of progressively slower timescales, the slow part of the correlator, $C_{\text{Aging}}(t, t')$, can be captured by a combination of involved functions each associated with a slow timescale.

Notably, by assuming the MF picture of aging as a starting point (such as Eq. 18), it is possible to investigate the properties of asymptotic regimes without explicitly solving the integro-differential equations for the correlation and response functions (e.g., Eqs. 19 and 20). The outcome is different depending on whether the low- T phase is 1-RSB or full-RSB. For the latter, a dynamical effective stochastic process for the slow-evolving effective part of Eq. (18) has been worked out, which exactly maps into the

ultrametricity condition associated with the Parisi solution in the replica formalism. Hence, DMFT both in the presence of a single slow timescale and in the ultrametric scenario explicitly links the aging dynamics with the replica-based description.

Spin glasses in three dimensions

Numerical methods

Although MF treatments provide elegant exact solutions for SGs defined on a fully connected or tree-like graph, extending those findings to three dimensions is quite challenging. For instance, even the existence of an SG phase in the 3d EAM has yet to be proven analytically. Most progress, therefore, arise from numerical simulations. In particular, there is convincing numerical evidence that, as their experimental counterparts, SG models in three dimensions exhibit a continuous phase transition at a temperature T_c .

The low-temperature dynamics of SGs is, however, very slow, due to the competition between short- and long-range interactions, and the presence of temperature chaos. In the SG phase, the free energy profile indeed changes drastically even for infinitesimal changes in temperature. The numerical study of SGs at low T is therefore highly challenging. Numerical strategies advanced for studying SGs notably include: the construction and use of special-purpose computers, GPUs, the formulation parallelization techniques, such as multi-spin coding, which, by encoding every spin on a single bit and restricting to bit-to-bit operations, allows one to simulate 64 replicas (the number of bits in a long integer) in the time of one; and the development of algorithms, such as *parallel tempering*, which consists of simultaneously simulating several replicas at different temperatures, and proposing Monte-Carlo updates, which exchange the temperatures among replicas.

Spatial correlations

A key feature of low-dimensional systems is the characteristic extent of spatial correlations, ξ . Its typical experimental determination is through the magnetic response to an external magnetic field h , which provides the coherence length ξ_{Zeeman} . In numerical simulations, the size of the correlated domains is instead calculated through correlation functions of the form

$$C(\mathbf{r}) = \frac{1}{N} \sum_{\mathbf{x}}^N q_{\mathbf{x}} q_{\mathbf{x}+\mathbf{r}}, \quad (21)$$

where $\mathbf{x}$ indicates a position in the lattice, $\mathbf{r}$ is a displacement vector, and $q_{\mathbf{x}}$ is usually the overlap at site $\mathbf{x}$, $q_{\mathbf{x}} = q_{\mathbf{x}}^{(ab)} = s_{\mathbf{x}}^{(a)} s_{\mathbf{x}}^{(b)}$, or the link overlap, $q_{\mathbf{x}} = q_{\text{link},\mathbf{x}}^{(ab)} = q_{\mathbf{x}}^{(ab)} q_{\mathbf{x}+\hat{e}}^{(ab)}$ ($\hat{e}$ is a unit vector) since these quantities are equivalent in the limit $d \rightarrow \infty$. There are several ways

to extract a correlation length ξ_{micro} from $C(\mathbf{r})$. For example, $\xi_{\text{micro}} = \sqrt{\frac{\int r^2 C(r) dr}{\int C(r)}}$. While, out of equilibrium, ξ_{Zeeman} and ξ_{micro} have different behaviors, and at equilibrium they match. These length scales can be used to identify phase transitions through finite-size scaling, by comparing simulations performed in systems of different linear sizes L . Because quantities such as $\frac{\langle \xi(T) \rangle}{L}$ are scale-invariant at T_c , one can identify critical points by investigating where the curves $\frac{\langle \xi(T) \rangle}{L}$ cross for different L . For the study of SGs, it has also proven useful to consider other quantities, such as ratios of susceptibilities, possibly conditioned to given values of the overlap.

The spin-glass phase in low dimensions

Pictures for the nature of the low-temperature phase in three dimensions

Just like there is no rigorous proof of the existence of T_c in three dimensions, there is no first-principles theory on the nature of the spin-glass phase in this case either³. Two main phenomenological scenarios have been proposed: the Droplet and the RSB pictures. The former is based on a renormalization group approach on the EAM, which is exact in one dimension, and depicts the SG phase as having only two pure states, with $q = \pm q_{\text{EA}}$, reminiscently of the behavior of the ferromagnetic Ising model. One consequence of this proposal is that the size of the surface separating different magnetic domains scales as L^{d_s} , with $d_s < d$ (for the Ising ferromagnet $d_s = d - 1$), and the energy of the smallest excitation grows with L . Another consequence is that the low-temperature phase disappears as soon as an external magnetic field is applied to the system.

The RSB picture is based on the opposite limit, $d = \infty$. It assumes that the SG phase of the EAM is qualitatively similar to that of the SK model, with an overlap distribution $P(q)$, which is nonzero over a wide interval of q . This picture prescribes that the domain surfaces are space-filling ($d_s = d$) and the smallest excitation remains $\mathcal{O}(1)$ when $L \rightarrow \infty$. In addition, the SG phase survives when a finite magnetic field is applied, with a dAT line $h_c(T)$ separating the paramagnetic from the SG phase (as described in Section “The replica method”). Whether either of the two theories holds remains, however, a matter of debate.

³The results in this section refer to the 3d EAM, which is the most studied model.

Evidence on the nature of the spin glass phase in 3d

Evidence to falsify or support the Droplet and RSB scenarios has principally been sought through numerical simulations. For example, equilibrium runs of the 3d EAM with linear size $L \leq 32$ deep in the SG phase show that $P(q)$ has wide support, and $P(0)$ is stable as L increases. This observation is in contradiction with the Droplet prediction, $P(q) \propto [\delta(q - q_{\text{EA}}) + \delta(q + q_{\text{EA}})]$, which assumes $P(0) = 0$.

When an external magnetic field is applied to the system, equilibrium simulations appear perturbed by finite-size effects, and there is disagreement on the existence of a dAT line. Arguments stemming from numerical simulations on the 3d EAM state that a phase transition could be present at temperatures that are 40% lower than those accessible. Those are opposed by arguments from simulations on SG chains with long-ranged interactions, which mimic 3d systems, claiming that no transition exists. We note, however, that the upper critical dimension is $d_{\text{up}} \geq 6$, and that there is strong evidence for a dAT transition in $d = 4$. Perturbative renormalization group analysis in $d = 6 - \varepsilon$ is consistent with the presence of a dAT line, with a nontrivial fixed point appearing at second order in ε .

Outlook on the nature of the spin glass phase

The current numerical evidence does not confirm the Droplet picture, but it has been argued that the observations might change if larger system sizes were simulated. It is to be noted, however, that times and system sizes of numerical simulations nowadays closely approach those of experiments. Therefore, if even there is a limit of very large L in which the Droplet theory applies, this might not be experimentally relevant. Evidence in favor of the RSB picture is, however, not decisive, and relevant beyond-MF mechanisms might arise in low dimensions. Alternative or intermediate scenarios could also be valid, such as the trivial-nontrivial picture, according to which the domain surfaces are not space-filling (as in the Droplet picture) but there are large-scale excitations whose energy does not increase with size (as prescribed by the RSB scenario).

Conclusion

Universality classes

While our discussion thus far focused on few specific SG models, changing details of the Hamiltonian can change general features of the energy landscape such that new physics emerges. As discussed above, dimensionality plays a crucial role, with the $d = 1, \infty$ limits having dissimilar behaviors that might both differ from $d = 3$. Altering the distribution of the couplings, $P(J_{ij})$, does not seem to influence the universality class of the models as long as they are not fat-tailed. Changing the interaction *range* is also a relevant perturbation, in that a system with longer ranged interactions is more MF like. This effect has notably led to the search for a correspondence between short-ranged high-dimensional models and long-ranged SGs in $d = 1$.

Another important is the nature of the spins. As described in Section “The replica method,” one can soften spins, passing from Ising to spherical spins. For pairwise interactions in $d = \infty$, this completely changes the landscape, which passes from complex to simple. (The dynamics nevertheless remains slow due to a large number of flat directions.) Alternatively, one can use spins that are normalized vectors with m components. For high m , the landscape becomes trivial, both in high- and low-dimensional systems, which points toward using the limit $m \rightarrow \infty$ for studies of the $1/m$ expansions. Because the $m \rightarrow \infty$ behavior seems radically different from any finite m , however, this approach has not been extensively pursued.

One can also consider Hamiltonians that mix interactions with different numbers of bodies, such as *mixed p-spin models*. These models display several crossover temperatures at which the dynamical behavior changes qualitatively, apparently without any thermodynamic transitions. This behavior is reminiscent of that of supercooled liquids.

An important aspect, which goes beyond the description of the specific model, is that over the years SGs have become a theoretical paradigm for modeling many different complex systems across disciplines, with an extremely broad spectrum of equilibrium and out-of-equilibrium properties. In fact, theories based on disordered systems often reveal to be beneficial for the treatment of problems outside the domain of SGs. Heterogeneous systems, either with quenched or self-generated disorder, are much more general than it might be believed at first glance, ranging from neural networks and optimization problems, signal reconstruction, random lasers, financial markets, topological superfluids, supercooled liquids, and jammed packings and theoretical ecology, and thermodynamic and dynamic formalisms rooted in spin-glass theory can still be used to solve them.

Open problems

SGs can be defined simply, but many questions remain open. We note: the nature of the SG phase [*does replica symmetry breaking occur in finite-dimensional systems?*]; their out-of-equilibrium behavior [*how and which length scales describe their evolution? how are equilibrium states related to the closest local minima?*]; or activated dynamics [*how does the dynamics take place at times $t \gg N$?; temperature chaos [how and why does the landscape change drastically even with small temperature changes and how can we harness it to obtain low-temperature configurations?]; the identification of metastates [can we explicitly measure the pure states of the SG phase?]; connection to other kinds of systems [can we map the SG behavior onto other systems such as supercooled liquids or deep neural networks?].*

These questions are not mere academic curiosities about a disordered magnetic alloy because—as it has happened several times in the past already—spin-glass theory can significantly impact other fields. We take theoretical ecology as a final example.

It is well known that the kind of sparsity of the interaction matrix of couplings between species has a crucial influence on the behavior of the ecosystem and that these couplings are typically sparse in nature. Therefore, if we could harness low-dimensional SGs, which, for example, have spatial fluctuations, our understanding of ecological and biological communities would significantly advance.

Abstract

A spin glass is a diluted magnetic material in which the magnetic moments are randomly interacting, with a huge number of metastable states which prevent reaching equilibrium. Spin-glass models are conceptually simple, but require very sophisticated treatments. These models have become a paradigm for the understanding of glassy materials and also for the solution of complex optimization problems. After cooling from the paramagnetic phase, the spin glass remains out of equilibrium, and slowly evolves. This aging phenomenon corresponds to the growth of a mysterious “spin-glass order,” whose correlation length can be measured. A cooling temperature step during aging causes a partial “rejuvenation,” while the “memory” of previous aging is stored and can be retrieved. Many glassy materials present aging, and rejuvenation and memory effects can be found in some cases, but they are usually less pronounced. Numerical simulations of these phenomena are presently under active development using custom-built supercomputers. A general understanding of the glassy systems, for which spin glasses bring a prominent insight, is still under construction.

Introduction

A spin glass is a set of interacting magnetic moments, originating from spins, in which the magnetic interactions are randomly distributed in sign. In the well-known case of ferromagnets, the interactions are positive, tending to align the moments along the same direction, and producing a net macroscopic magnetization. In antiferromagnets, the interactions are negative, driving the moments to anti-alignment, and establishing a set of two interpenetrating ferromagnetic sublattices, oriented in opposite directions.

We can simply describe the case of spin glasses as a mixture of both ferro- and antiferromagnetic situations. The theoretical definition of the spin glass is that of an ensemble of randomly interacting magnetic moments. The total energy H is the sum over interacting neighbors ($S_i S_j$) of the coupling energies $J_{ij} S_i S_j$, where the $\{J_{ij}\}$ are random variables, usually gaussian or $\pm J$ distributed (Edwards and Anderson, 1975):

$$H = - \sum_{i,j} J_{ij} S_i S_j \quad (1)$$

The magnetic moments (or spins) are in random sign interactions, that is, each moment experiences contradicting constraints from its neighbors. This situation of contradicting influences has been termed *frustration*. No simple symmetric configuration of the set of spins corresponds to an equilibrium state. Conversely, the abundance of different spin configurations which have similar energy values produces a huge number of metastable states. The states are separated by free-energy barriers of all heights, which generate a very wide spectrum of response times, from paramagnetic times ($\approx 10^{-12}$ s) up to astronomical scales. Finding the absolute minimum is thus extremely difficult and, from a practical point of view, a spin glass is virtually always out of equilibrium. At low temperature, the spin glass is in a (partially) frozen phase, but this state slowly evolves, with no apparent time limit (for a comprehensive presentation of spin glasses and other disordered magnetic systems, see Nordblad, 2023).

In a spin glass, the disorder lies in the magnetic interactions, which are fixed. Contrary to this situation of a so-called *frozen* disorder, the disorder in usual (structural) glasses lies in the random positions of the molecules. A structural glass is a frozen liquid, in which the molecules are slowly moving, thereby changing the disorder configuration. The spin glass problem, with frozen disorder, is conceptually simpler. It has allowed rich, far-reaching theoretical developments: mean-field treatment by Sherrington and Kirkpatrick (1975), with a solution by Parisi in a model with “continuous RSB,” standing for *continuous replica symmetry breaking*, a sophisticated mathematical method (Parisi, 1979; Mezard et al., 1987; Altieri and Baity-Jesi, 2023). The numerical simulations have brought many results, up to spectacular recent progresses by the Janus collaboration with special-purpose supercomputers (Baity-Jesi et al., 2018; Zhai et al., 2020; Baity-Jesi et al., 2022). Although involving different natures of disorder, both spin glasses and structural glasses share a lot of similitudes, and the spin glass is usually considered a powerful model for the description and understanding of various glassy materials, among which “ferroic” materials have recently received a particular interest (Lookman and Ren, 2018; Ji et al., 2023).

The first studied spin-glass materials were non-magnetic metals (Au, Ag, Pt...) in which a few percent of magnetic atoms (Fe, Mn...) were dispersed at random (Cannella and Mydosh, 1972). The magnetic atoms are separated by random distances, and the oscillating character of the Ruderman-Kittel-Kasuya-Yosida (RKKY) interaction with respect to distance makes their coupling energies take a random sign. As explained in Mydosh (1993), the term “spin glass” was first suggested by B.R. Coles in 1970 to be applied to the strange magnetic behavior of an Au:Co alloy, and appeared again at Coles’ instigation in Anderson (1970). Examples of spin glasses have also been found within diluted magnetic insulators with shorter-ranged interactions (Alba et al., 1982). Although chemically very different, these various compounds have been found to show a common general behavior that is now understood as generic for spin glasses. A fairly comprehensive review of the theoretical and experimental aspects of spin glasses can be found in Kawamura and Taniguchi (2015). Another interesting review has been given by Mydosh (2015), with emphasis on new spin glass materials and related topical problems in condensed matter physics.

The spin-glass phase

The spin-glass phase forms below a characteristic glass temperature T_g , whose magnitude is governed by the strength of the interactions. At temperatures T much higher than T_g , thermal magnetic fluctuations dominate against interactions, and the spins are fluctuating paramagnetically (Fig. 1A). The magnetization M obtained under a low field H follows a Curie-Weiss law.

$$M/H \propto C/(T-\theta) \quad (2)$$

which is characteristic of a paramagnetic phase (C is proportional to the square of the individual magnetic moments, and θ is a temperature proportional to the energy of the interactions).

A frozen state

Below T_g , the magnetic behavior as a function of temperature becomes history-dependent, the spins are in a frozen phase. In the “FC” (field-cooled) procedure, a magnetic field is applied above T_g , and $M(T)$ is measured upon slowly cooling in the field. The same $M(T)$ curve is obtained upon re-heating, the FC curve is usually stable within 1%, and is mostly flat.

Fig. 1 Typical magnetic characterization of a spin glass (Dupuis, 2002). The sample is an insulating spin glass prepared by M. Noguès (Alba et al., 1982). Left (A): *dc* measurements. Above the glass temperature $T_g = 16.7$ K, the magnetization has a paramagnetic shape. In the spin-glass phase, below T_g , the field-cooled (FC) and zero-field cooled (ZFC) curves are split, showing a history-dependent behavior. Right (B): *ac* measurements. The in-phase component χ' of the *ac* susceptibility has a peak at a frequency-dependent freezing temperature. The out-of-phase (dissipative) component χ'' is null in the paramagnetic phase, and rises up when entering the spin-glass phase.

On the other hand, in the “ZFC” (zero-field cooled) procedure, the sample is cooled in zero field, and the field is applied at the lowest temperature. Since the spins are in a frozen state, the magnetization cannot reach an equilibrium value (which we consider to be the FC value). It slowly increases with time. Then, as we increase the temperature, the magnetization curve $M(T)$ progressively rises up, finally merging with the FC curve in the vicinity of T_g .

Fig. 1A shows typical FC-ZFC measurements (Dupuis, 2002). When cooling from the paramagnetic phase, the magnetization rises up, until reaching T_g , below which the FC curve is essentially flat. This apparent “solidification” of the spin system at T_g , with no further significant evolution of the magnetization, suggests a collective behavior of the spins, with a sudden freezing into a long-range correlated state. We show below that the process of freezing at T_g presents a critical character, and we describe how this amazing glassy ordered state of matter can be characterized.

We can also explore the spin-glass phase by means of *ac* field measurements, which usefully complete the *dc* procedures described above. When a weak *ac* magnetic field is applied, the observed *ac* susceptibility χ is usually decomposed into two components: χ' (in-phase component), and χ'' (out-of-phase, or dissipative, component). Fig. 1B shows the *ac* susceptibility of a spin glass at frequency $\omega/2\pi = 0.4$ Hz, as a function of temperature (Dupuis, 2002). χ' has the same shape as the ZFC (*dc*) magnetization in Fig. 1A, which can be thought as an *ac* measurement at a frequency that is the inverse of the time spent at each heating temperature step in the ZFC curve.

The out-of-phase response χ'' is null above T_g , in the paramagnetic phase the spins are oscillating in phase with the excitation field. Upon cooling down, the approach of T_g is signalled by a sharp increase of χ'' : the magnetic response is delayed, the spin system is freezing.

Critical dynamics of freezing

The χ' peak coincides with the inflection point of the χ'' rise. It takes place at a freezing temperature $T_f(\omega)$ which depends on the frequency $\omega/2\pi$: for higher frequencies, higher freezing temperatures are observed, in the same way as, on a photo taken with a shorter aperture time, faster events can be seen being still. We consider that T_g is the zero-frequency limit of $T_f(\omega)$. Studying the frequency dependence of $T_f(\omega)$ allows checking whether the freezing transition at T_g is a dynamical process (like for independent superparamagnetic particles), or presents the collective character of a thermodynamic phase transition (Tholence, 1981).

If the freezing process at T_g is a collective process, then there should be a divergence of a correlation length ξ at the approach of the transition at T_g , according to:

$$\xi = \xi_0 [(T_f(\omega) - T_g)/T_g]^{-\nu} \quad (3)$$

(ν being the usual critical exponent for the correlation length at a phase transition). The dynamic scaling hypothesis states that the response time τ of a spin ensemble of size ξ goes like

$$\tau \propto \xi^z, \quad (4)$$

where z is defined as a dynamical exponent. In this way we obtain the critical dynamics scaling relation (Binder and Young, 1984):

$$\tau = \tau_0 [(T_f(\omega) - T_g)/T_g]^{-z\nu} \quad (5)$$

The precise frequency dependence of $T_f(\omega)$ has been studied in many spin-glass examples. It clearly shows a divergence of the response times as ω goes to zero, attesting the critical character of the freezing process at T_g . The value of the exponent $z\nu$ ranges from

5 to 11 in the various samples (Bontemps et al., 1984; Vincent and Hammann, 1986; Kawamura and Taniguchi, 2015). This collective behavior of the interacting spins at the spin-glass transition marks an important difference with other classes of freezing processes. As an example, for non-interacting superparamagnetic nanoparticles, the freezing process involves response times τ which follow an Arrhenius law.

$$\tau = \tau_0 \exp(U/k_B T) \quad (6)$$

The superparamagnetic fluctuations of the nanoparticles are freezing because of thermal slowing down due to their individual anisotropy barriers U . On the contrary, if the nanoparticles are concentrated enough to have significant magnetic interactions, they form a *superspin* glass that has also been well characterized (Dormann et al., 1996; Nakamae et al., 2012).

A genuine thermodynamic phase transition

In order to complete the characterization of a critical behavior in the dynamics, it is interesting to check whether the spin-glass transition also presents a critical character for static quantities. In a ferromagnet, the order parameter is the spontaneous magnetization, and the order parameter susceptibility is the usual magnetic susceptibility. In a spin glass, defining an order parameter of the “glassy order” is not straightforward. A theoretical definition has been proposed by Edwards and Anderson (1975), in which the order parameter is the average over the sample of the squared moduli of the spins. The corresponding order parameter susceptibility has been shown to be the non-linear part of the magnetic susceptibility (Suzuki, 1977; Chalupa, 1977; Suzuki and Miyashita, 1981). The dc magnetic susceptibility χ can be expanded in even powers of the magnetic field H :

$$\chi = \chi_0 - a_3 H^2 + a_5 H^4 \dots, \quad (7)$$

χ_0 being the linear susceptibility. The coefficients of the non-linear terms are expected to diverge at T_g , with the critical exponents β, γ corresponding to the spin glass order parameter:

$$a_3 \propto (T - T_g)^{-\gamma}, a_5 \propto (T - T_g)^{-(\beta + \gamma)}, \text{etc.} \quad (8)$$

Their determination implies extensive measurements of the magnetic susceptibility as a function of the field, at various temperatures close to T_g , and careful extrapolation to zero field. Fig. 2 shows the example of Ag:Mn_{0.5%} (Bouchiat, 1986). The non-linear part of the susceptibility is plotted as a function of the field. As the temperature T decreases toward T_g , a significant increase of the initial slope of the curves is clearly visible. Below $1.1T_g = 2.97$ K, the low-field behavior of the non-linear susceptibility goes from

Fig. 2 Non-linear susceptibility (obtained as the difference ΔM between the total magnetization and its field-linear part, divided by the applied magnetic field H), as a function of field H , at different temperatures approaching the critical temperature $T_g = 2.70$ K. The relative origins on the Y-axis are arbitrary. 1% of the linear susceptibility χ_0 is indicated. As $T \rightarrow T_g$, a sharp increase of the slope at the origin is clearly visible, pointing to a divergence of the coefficients in the non-linear susceptibility (Eqs. 7–8). From Bouchiat H (1986) Determination of the critical exponents in the Ag Mn spin glass. *Journal de Physique* 47: 71–88.

quadratic to singular. This increase (together with the analysis of other data) allows the characterization of the diverging character of a_3, a_5 (Eqs. 7-8), and a coherent determination of the critical exponents β , γ , δ . Similar results have been obtained in numerous different spin glass samples (see references in Kawamura and Taniguchi, 2015). Thus, the transition to the spin-glass phase has the same characteristics as a genuine thermodynamic transition to an ordered state.

The non-linear susceptibility can also be accessed through the study of the harmonics in the response to an ac field. Pioneering measurements of the 3rd harmonics have been performed by Miyako et al. as early as in 1979. Lévy (1988) determined the whole set of critical exponents of AgMn samples by carefully measuring the 3rd, 5th and even 7th harmonics of the ac susceptibility.

The spin-glass transition: Open questions

The critical character of the spin-glass transition, which takes place in a fully disordered system, raises a number of issues. From the critical dimensions obtained in the mean-field theory of spin glasses, in $d = 3$ a phase transition is expected for Ising (scalar) spins, but not for Heisenberg (vector) spins (Mezard et al., 1987, and references therein). However, a phase transition is found in real $d = 3$ spin glasses, and it has been observed as well with Ising as with Heisenberg-like spins. A way to an explanation can be found in the scenario proposed by Kawamura of a chirality driven phase transition of spins (1-step-like RSB class model). This mechanism has been detailed and argued both analytically and numerically. A remarkable agreement of the predicted critical exponents with the experiments has been found (Kawamura, 1992; Kawamura and Taniguchi, 2015). A direct experimental access to chirality freezing is difficult, but some pioneering measurements of the anomalous Hall effect in spin glasses have already given very interesting results (Pureur et al., 2004; Taniguchi, 2007).

In the Parisi solution of the mean-field Ising spin glass (Parisi, 1979), an infinite number of different pure states is obtained, yielding a complex structure of the spin glass phase (this class of models corresponds to a continuous RSB, also called full-RSB, see in Mezard et al., 1987, Altieri and Baity-Jesi, 2023). It suggests that, after cooling from the paramagnetic phase, many domains with different types of spin-glass order should coexist and compete. A phase diagram with a transition line is obtained as a function of the magnetic field. On the other hand, with a very different point of view, scaling theories of the spin-glass behavior have been developed for Ising spins (droplet model by Fisher and Huse, 1988a, b; domain model by Koper and Hilhorst, 1988). In these models, there are simply two (spin reversal symmetric) pure states, and the phase transition is expected to be destroyed by any magnetic field. Let us briefly comment on these questions at the light of the experimental results.

- (i) The question of a multiple or single nature of the ground state in the spin glass is very difficult to address directly in experiments, in which no ground state is ever reached. Some arguments are given in the discussion on the temperature dependence of aging effects (Section “Domain growth and hierarchy of states”). A more direct way can be searched from the theoretical suggestion by Carpentier and Orignac (2008), stating that the correlation of the conductance fluctuations in two spin states should be a direct function of their overlap. A new experimental approach using transport measurements on mesoscopic samples has started (Capron et al., 2013). Measurements of the universal conductance fluctuations in mesoscopic spin glasses are challenging, but they can be a promising way to obtain information on the nature of the pure states. Resistivity measurements on mesoscopic wires are now on the way (Forestier et al., 2020).
- (ii) The vanishing of the phase transition in presence of a magnetic field has been reported in a study of critical dynamics on a $\text{Fe}_{0.5}\text{Mn}_{0.5}\text{TiO}_3$ single crystal, which is a good example of a short-range Ising spin glass (Mattsson et al., 1995). Interestingly, recent experiments on $\text{Dy}_x\text{Y}_{1-x}\text{Ru}_2\text{Si}_2$ show that the phase transition persists in a field in this example of an Ising but long-range (RKKY) system (Tabata et al., 2017). For Heisenberg-like spin glasses, data from torque measurements bring robust evidence for a true spin glass ordered state that survives under high applied magnetic fields (Petit et al., 2002).

The nature of the glass transition is also a hot topic for structural glasses. We now understand that the non-linear dielectric susceptibility plays a similar role as in spin glasses (Bouchaud and Biroli, 2005). It has been recognized for a long time that the drastic dynamical slowing down at the glass transition of the most “fragile” glasses can be compared with the critical slowing down observed in spin glasses (Souletie and Bertrand, 1991). Non-linear dielectric susceptibility measurements in glycerol and other viscous liquids have now allowed determining the growth of correlations at the approach of the transition and in the glassy phase during aging (Brun et al., 2012; Albert et al., 2019).

In experiments on spin glasses, what we see is essentially an out-of-equilibrium behavior, with many interesting properties. We now describe some of them.

Slow dynamics and aging in spin glasses

Relaxation of the magnetization

After cooling the spin glass from above to below T_g in a field, we reach a state in which the magnetization is approximately constant (FC state, Fig. 1A). There are some signs that this frozen state is not at equilibrium. If we now turn the magnetic field to zero, the magnetization does not go to zero value, which for symmetry reasons should be the equilibrium value. The non-zero remanent magnetization obtained in this procedure, called *thermo-remanent magnetization* (TRM), slowly relaxes as a function of time. Such TRM curves are shown in Fig. 3 on a logarithm time scale.

Fig. 3 Relaxation of the thermo-remnant magnetization (TRM) of the Ag:Mn_{2.7%} spin glass. The procedure is sketched in the inset. The magnetization decay curves obtained for 5 t_w values ranging from 300 s to 30,000 s are presented on a logarithmic scale, as a function of t/t_w to emphasize their t_w -dependence (called “aging”). Data from the Saclay group, figure from Vincent E, Hammann J, Ocio M, Bouchaud J-P, and Cugliandolo LF (1997) Slow dynamics and aging in spin glasses, in: *Complex Behaviour of Glassy Systems*, Rubi M (ed.), Berlin: Springer-Verlag Lecture Notes in Physics, 492: 184.

These experiments involve a second time parameter called the *waiting time* t_w (inset of Fig. 3). The sample is rapidly cooled in a weak field $H = 0.1$ Oe from above T_g to $T = 0.87T_g$ (quench), and is kept at temperature T during a given t_w (5 values from 300 to 30,000 s in Fig. 6). After waiting t_w , the field is cut, and the relaxation is measured as a function of the observation time t elapsed since the field cut-off. The inflection point of curves (maximum of the relaxation rate) shifts toward longer times as t_w increases, always taking place around $t \approx t_w$. Presented as a function of the ratio t/t_w , they are almost superimposed. So, after a longer waiting time t_w , the response to the field change becomes slower, with characteristic times of the order of t_w itself. The spin-glass phase has been evolving during the time spent below T_g (it has become “more frozen”), although the FC-magnetization remains roughly constant. This phenomenon is called *aging* (from similar effects observed in polymer mechanics, Struik, 1978).

When studied in more details, the t_w effect can be accurately taken into account. The shift between the curves obtained for different t_w 's is not exactly $\log t_w$, but rather $\mu \cdot \log t_w$, μ being a sample-dependent coefficient of order 0.8–0.9. Hence, the relevant variable is t_w^μ , and when it is properly accounted the relaxation curves can all be superimposed very precisely (Ocio et al., 1985a; Vincent et al., 1997; see an example in the inset of Fig. 5 below).

We want to emphasize that the magnetic field applied in these experiments is weak (0.1–10 Oe), that is, not larger than a few percent of the value that, at low temperature, would bring the spin glass back to the paramagnetic phase. Such a weak field has a negligible effect on the properties that we describe here, linear response is obeyed, the field can be considered as a non-disturbing probe field. This will not hold for higher values of the field (see Fig. 2.8 in Vincent, 2007). Interestingly, some differences in the dynamics of the spin-glass phase with and without a field have recently been characterized very close to T_g , both in experiments and numerical simulations (Paga et al., 2022). In the field and temperature range of the measurements presented here, no difference was visible within the experimental accuracy.

It can also be useful to clarify that aging during t_w is not related to the presence of the field. The mirror procedure of the TRM experiment can be performed with the same conclusions. Cooling the sample in zero field from above T_g , waiting t_w at low temperature, and applying a field in the ZFC state yields a $ZFC(t)$ relaxation which is the mirror image of the $TRM(t)$ curve, and presents the same t_w -dependence. It has been demonstrated that $ZFC(t_w, t) + TRM(t_w, t) = FC$ (this relation even holds when a slight relaxation of the FC magnetization can be seen, $FC \equiv FC(t)$) (Djurberg et al., 1995).

The phenomenon of aging has been known for a long time in the mechanical properties of a wide class of materials called “glassy polymers”. When a piece of e.g. PVC is submitted to a mechanical stress, its response (elongation, torsion ...) is logarithmically slow. And the response depends on the time elapsed since the polymer has been quenched below its freezing temperature. Like in spin glasses, for increasing aging time the response becomes slower. The t_w^μ -dependence of the dynamics of glassy polymers has been expressed as a scaling law (Struik, 1978) that could be applied successfully to the case of spin glasses (Ocio et al., 1985a). Numerous glassy materials show similar aging phenomena. Numerical simulations of packed hard spheres provide us with very powerful toy models of simple glasses (Jin and Yoshino, 2017).

Magnetic noise

We have shown above how aging in spin glasses can be studied by measuring the waiting time dependence of the magnetic response to cutting a magnetic field at low temperature (TRM relaxation). In statistical mechanics, the response to a field change is related to the spontaneous fluctuations by the Fluctuation-Dissipation theorem (FDT), established for ergodic systems at equilibrium (see references in Hérisson and Ocio, 2002, 2004). Applying FDT to the situation of TRM experiments, we can relate the relaxation function $\sigma(t', t)$ ($\sigma = M/H$, magnetic response at t after cutting off a field H at t') to the autocorrelation C of the fluctuations of the magnetization m , namely $= \langle M(t') \cdot M(t) \rangle$:

$$\sigma = C/k_B T, \quad (9)$$

with k_B being the Boltzmann constant.

Fig. 4 The signal from the SQUID detector, proportional to the magnetization with an arbitrary offset, is shown as a function of time in a series of successive noise recording experiments. The spontaneous fluctuations of the magnetization (magnetic noise) are observed here in the absence of any excitation. Data from Hérisson D. and Ocio M. (2004) Off-equilibrium fluctuation-dissipation relation in a spin glass. *European Physical Journal B* 40: 283.

Fig. 5 TRM-relaxation (bottom), and noise autocorrelations functions presented in the same fashion as the TRM curves (top). The different curves correspond, in ascending order, to 5 values of the waiting time t_w , increasing from 100 to 10,000 s. The insets show a superposition of the aging part of the curves using the scaling procedure of Ocio et al., 1985a (see also Vincent et al., 1997). This double figure allows an overall comparison of the response and autocorrelation functions, which are related by the Fluctuation-Dissipation Theorem (FDT). The experiment aims at testing FDT in the non-equilibrium conditions of aging. Data from Hérisson D and Ocio M (2004) Off-equilibrium fluctuation-dissipation relation in a spin glass. *European Physical Journal B* 40: 283.

Fig. 6 Response function versus autocorrelation (so-called “FDT plot”), for 3 different temperatures T . The straight lines show the $1/T$ equilibrium regime of FDT. The points are the raw results. The solid curves are a long time extrapolation of the data, which is necessary for a comparison with the mean-field theory. The dashed line is a fit to $\chi = (1-C)^{0.47}$, in reference to the continuous RSB model (Marinari et al., 1998). From Hérisson D and Ocio M (2004) Off-equilibrium fluctuation-dissipation relation in a spin glass. *European Physical Journal B* 40: 283.

The measurement of the spontaneous fluctuations of the magnetization (“magnetic noise”) in spin glasses is very difficult because of a very weak signal. Yet, it has been a strong motivation for the experimentalists to check how far FDT can be obeyed in the out-of-equilibrium situation of the spin glass, for which the aging regime is considered archetypal. Pioneering measurements started early (Ocio et al., 1985b). Later on, important theoretical efforts have been devoted to extensions of FDT to non-equilibrium situations (see for example Franz et al., 1998). A prominent result by Cugliandolo and Kurchan (1994) and Cugliandolo et al. (1997) is a modified FDT relation which reads

$$\sigma = C \cdot F(C)/k_B T \quad (10)$$

where $T/F(C)$ takes the meaning of an *effective temperature* T_{eff} , different from the sample temperature T . In this approach, for large t' , the obtained correction factor $F(C)$ is a function of the autocorrelation C only, i.e. it does not explicitly depend on t and t' , but has a time dependence through the value of $C(t',t)$ only. Hérisson and Ocio (2002, 2004) have built a special purpose SQUID magnetometer in which response and fluctuations could both be measured in the same geometry. Important care was taken for eliminating all electromagnetic parasite sources.

An example of noise recordings is presented in Fig. 4, from the $\text{CdCr}_{1.7}\text{In}_{0.3}\text{S}_4$ thiospinel sample. Each trace shows the SQUID output (proportional to the sample magnetization, with an arbitrary offset) during one experiment, starting from above T_g and cooling. Due to a slight residual field, the trace shows the magnetization peak observed when crossing T_g . After cooling, the temperature is stabilized at $T = 0.7T_g$, and the magnetization fluctuations are recorded as a function of time during $\sim 10^4$ s. After that the sample is re-heated above T_g . The experiment is repeated ~ 300 times. On each of the recorded traces, for any choice of times (t_w, t) the correlation $M(t_w) \cdot M(t_w + t)$ can be computed. This value is strongly fluctuating from one experiment to the other, but the average over ~ 300 measurements is taken and after properly subtracting offsets the noise autocorrelation $C(t_w, t) = \langle M(t_w) \cdot M(t_w + t) \rangle$ is obtained.

Fig. 5 (bottom part) shows TRM experiments performed in the same setup, with a very small excitation field of $\sim 10^{-3}$ Oe. Fig. 5 (top part) shows the noise autocorrelation, presented in the same way as the TRM results, as a function of t for various fixed values of t_w .

Both sets of results present the same overall shape, but a precise comparison is best illustrated in the plot of Fig. 6 (sometimes called “FDT plot”), in which the response function $\sigma(t_w, t)$ (or the susceptibility $\chi = 1 - \sigma$) is plotted as a function of $C(t_w, t)$ for 3 different temperatures $T = 0.6, 0.8$ and $0.9T_g$. For each of the 3 temperatures, the point cloud is the set of “raw” results obtained for various values of (t_w, t) . The straight lines with $1/T$ slope show the prediction for classical FDT with no correction. There is a clear $1/T$ regime for the higher values of C , and a crossover toward a weaker slope $1/T_{\text{eff}}$ with $T_{\text{eff}} > T$ as C decreases. These deviations show the first experimental observation in a spin glass of deviations from the normal FDT in the aging regime (Hérisson and Ocio, 2004).

The results in Fig. 6 strongly suggest that the correction factor $F(C)$ to FDT is only a function of C , as predicted by Cugliandolo and Kurchan (1994) and Cugliandolo et al. (1997). They allow a comparison with different models of the spin-glass phase, provided that a long-time extrapolation of the data can be made (see more details in Hérisson and Ocio, 2004). The observed mean slopes correspond to $T_{\text{eff}}(0.6T_g) \sim 1.5T_g$, $T_{\text{eff}}(0.8T_g) \sim 3T_g$, and $T_{\text{eff}}(0.9T_g) \sim 4T_g$. An infinite T_{eff} value (horizontal slope of the data), as expected in domain growth type models (Barrat, 1998) like the droplet model (Fisher and Huse, 1988a, b), seems to be very unlikely. In models like the mean-field spin glass with continuous RSB (Mezard et al., 1987), a $\chi = (1-C)^{1/2}$ behavior is predicted. The dashed line in Fig. 6 shows a $\chi = (1-C)^{0.47}$ fit (Marinari et al., 1998) which gives at least a rough account of the results. However, in their 2004 paper, Hérisson and Ocio comment on the possibility of also analyzing the results on the basis of a 1-step RSB model, confirming a possible relevance of the chiral scenario proposed by Kawamura (1992).

Aging, rejuvenation and memory effects

Temperature step experiments

The cooling rate has a strong influence on the state of a structural glass: slower cooling yields smaller values of the enthalpy and specific volume, which are closer to equilibrium values (Struik, 1978; Simon and McKenna, 1997; Ediger and Harrowell, 2012). In the case of spin glasses, can we play with the cooling rate, or design clever temperature procedures, in order to bring the spin glass closer to equilibrium? This question was the starting point of a class of experiments (Refregier et al., 1987), which have led to the observation of the astonishing phenomena of rejuvenation and memory (see a review in Vincent, 2007; Vincent and Dupuis, 2018).

Aging can also be observed in *ac* susceptibility measurements (like in Fig. 1B). After cooling from the paramagnetic phase to some fixed temperature in the spin-glass phase, both components χ' and χ'' are seen to slowly relax downwards due to aging. The variation in relative value is more important for the out-of-phase susceptibility χ'' (Dupuis, 2002; Vincent and Dupuis, 2018), therefore most experiments have focused on the measurement of χ'' . Fig. 7 presents an *ac* experiment in which temperature steps have been applied during aging (Lefloch et al., 1992).

After a normal cooling (~ 100 s) from $1.3 T_g$ to $0.7 T_g = 12$ K ($T_g = 16.7$ K), the sample is kept at the constant temperature of 12 K for $t_1 = 300$ min. During this time, χ'' shows a strong downwards relaxation (aging). After 300 min, the temperature is lowered one step further from $T = 12$ K to $T - \Delta T = 10$ K. What is then observed is a χ'' jump and a renewed relaxation. This behavior upon further cooling was termed *rejuvenation*, because the restart of the relaxation suggests that aging is starting anew at $T - \Delta T$. Apparently, there is no influence of former aging at T . The rejuvenation effect is at variance with the common expectation that a slower cooling rate should help approaching equilibrium. Waiting t_1 at T did not help approaching equilibrium at $T - \Delta T$.

One may naturally ask whether this renewed relaxation corresponds to a full rejuvenation of the sample. The answer is no. Two remarks should be made at this point:

- Clearly, for continuity reasons, the amount of rejuvenation must be modulated by the value of ΔT . A restart cannot be expected after a tiny temperature variation. The temperature interval must be sufficiently large, here we need $\Delta T \geq 2$ K.
- We should keep in mind that the time window explored in an experiment is limited, whereas the aging state of the spin glass involves relaxation processes on a very wide time range. Hence, from this sole experiment we do not have the knowledge of the overall state at all time scales.

The final part of the measurement completes the answer to the question of the occurrence of a full rejuvenation. After observing the renewed relaxation during $t_2 = 300$ min at $T - \Delta T = 10$ K, the temperature is turned back to $T = 12$ K. Then, what we see is that χ'' goes up to the point that was attained at the end of the stay at the original temperature T . And the relaxation continues in precise continuity of the former one, as if nothing of relevance for the state at T had happened at $T - \Delta T$. This can be checked by shifting the third relaxation to the end of the first one (inset of Fig. 7): they are in continuity, and can be superposed on the reference curve which has been separately measured in simple aging at constant $T = 12$ K.

Hence, during aging at $T - \Delta T$ and despite the strong associated χ'' -relaxation, the spin glass has kept a *memory* of previous aging at T . This memory is retrieved when heating back to T . This experiment made with $\Delta T = 2$ K illustrates in a spectacular manner the phenomenon of rejuvenation and memory in a spin glass. For smaller ΔT values, the situation is obviously more complex: one finds a weaker rejuvenation, and some mutual influence of aging at both temperatures ("cumulative" aging at both temperatures, similar to a cooling rate effect). Details on the results in this regime of small temperature variations, together with their discussion in terms of a random energy model, can be found in Sasaki et al. (2002). A wide set of experiments have been performed by the Saclay group

Fig. 7 AC experiment at 0.01 Hz, relaxation of the out-of-phase susceptibility χ'' during a negative temperature cycle following a temperature quench. The points show aging at 12 K, rejuvenation at 10 K, and memory at 12 K. The inset shows that, despite rejuvenation at 10 K, both relaxations at 12 K are in continuity of each other (memory). The sample is the $\text{CdCr}_{1-x}\text{In}_{0.3}\text{S}_4$ thiospinel spin glass ($T_g = 16.7$ K). From Lefloch F, Hammann J, Ocio M, and Vincent E (1992) Can aging phenomena discriminate between the droplet model and a hierarchical description in spin glasses? *Europhysics Letters* 18: 647–652.

(see references in Vincent, 2007) and by the Uppsala group (see, for example, Jönsson et al., 2002), with similar results, although sometimes discussed in slightly different terms regarding the comparison with the droplet model (Fisher and Huse, 1988a, b).

Very recently, Zhai et al. (2022) could accurately measure the effect of temperature variations on the tiny relaxation ($\approx 0.5\%$) of the FC magnetization in a CuMn spin glass. They can precisely distinguish a regime of cumulative aging for small temperature variations, and another one obtained for larger temperature variations, which shows some rejuvenation of the relaxation and is discussed in terms of “temperature chaos,” a theoretical notion which corresponds to an extreme sensitivity of the glass to temperature changes (Bray and Moore, 1987).

Multiple memories

The ability of the spin glass to keep a memory despite rejuvenation has been further explored in experiments with multiple temperature steps. The first *memory dip* experiments, suggested by P. Nordblad, were developed in a collaboration between the Uppsala and Saclay groups (Jonason et al., 1998, 2000). An example of a “multiple dip” experiment is shown in Fig. 8 (Bouchaud et al., 2001; Dupuis, 2002). This is a χ'' measurement in which the sample is cooled from above T_g to 4 K by steps of 2 K, with a stop at each step. Then, the sample is reheated continuously (inset of Fig. 8). Starting from $T > T_g$ where $\chi'' = 0$ (paramagnetic phase), χ'' rises up when crossing $T_g = 16.7$ K, and when the cooling is stopped at 16 K, 14 K, etc., the relaxation of χ'' due to aging is recorded during 30 min.

After waiting 30 min at constant temperature, upon further cooling by another 2 K step, a χ'' jump of rejuvenation is found, and the relaxation due to aging again takes place. At each new cooling step, rejuvenation and aging are seen, and this happens ~ 6 times in the experiment of Fig. 8.

In the second part of the experiment, the sample is re-heated continuously at a slow rate (0.001 K/s, equal to the average cooling rate). Amazingly, apart from the rather noisy low- T region, the memory of each of the aging stages performed during cooling is revealed in shape of “memory dips” in $\chi''(T)$, tracing back the lower value of χ'' which was attained at each of the aging temperatures. Thus, the spin glass is able to keep the simultaneous memory of 5 or 6 aging stops in a row, performed at lower and lower temperatures. The curve obtained while increasing the temperature after that reveals the memories (and meanwhile erases them).

Domain growth and hierarchy of states

In the droplet model (Fisher and Huse, 1988a, b), the spin glass is thought in the same terms as a ferromagnet, having two symmetric equilibrium states of opposed spin directions (with no trivial ordered alignment of the spins). Aging is described as the slow growth of domains of this “spin-glass order” of hidden symmetry, starting from the random configuration created by the quench from the paramagnetic phase. In a naive interpretation, domain growth processes should progress continuously during temperature variations, with some influence of temperature on the growth rate, similar to cooling rate effects. But, in that case, it is difficult to imagine how rejuvenation and memory effects may arise. In the droplet model, they are related to “temperature chaos” effects (Bray and Moore, 1987). Discussions on the relevance of this scenario to experiments can be found in Yoshino et al. (2001)

Fig. 8 An example of multiple rejuvenation and memory steps. The inset is a sketch of the procedure. The sample was cooled by 2 K steps, with an aging of time of 30 min at each step, after which rejuvenation can be seen (open blue diamonds). Continuous reheating at 0.001 K/s (full red circles) shows memory dips at each temperature of aging. The solid black line shows a reference measurement with continuous cooling/heating and no steps. From Dupuis V (2002) *Dynamique lente des systèmes magnétiques désordonnés*, PhD Thesis, Orsay University (France), <https://tel.archives-ouvertes.fr/tel-00002623/document>; Bouchaud J-P, Dupuis V, Hammann J, and Vincent E (2001) Separation of time and length scales in spin glasses: Temperature as a microscope. *Physical Review B* 65: 024439.

and Jönsson et al. (2004). The notion of a growing size of cooperative regions, encountered in many glassy systems, as well in experiments as in theoretical models, may well be at the heart of aging phenomena, as detailed by Corberi et al. (2011).

The theoretical ingredients that are necessary for rejuvenation and memory effects to arise are not yet well determined. Early studies of frustrated magnetic systems have shown that average effective interactions can be defined, which may present a strong temperature dependence (Miyashita, 1983). The temperature variation of the effective interactions can cause rejuvenation effects (Miyashita and Vincent, 2001). Still, the preservation of memory despite rejuvenation requires considering other processes in addition (Tanaka and Miyashita, 2005).

On the other hand, a different point of view has been proposed by the Saclay group to account for the rejuvenation and memory effects. The guideline is to consider a hierarchical organization of the metastable states as a function of temperature, inspired by the hierarchical organization of the pure states in the Parisi solution of the mean-field spin glass (Mezard et al., 1987;). Indeed, it could be shown that rejuvenation and memory effects can be expected in the dynamics of this model (Cugliandolo and Kurchan, 1999).

In this scheme, pictured in Fig. 9 (Dotsenko et al., 1990; Refregier et al., 1987), the effect of temperature changes is represented by a modification of the free-energy landscape of the metastable states (not only a change in the transition rates between them). At fixed temperature T , aging corresponds to the slow exploration of the numerous metastable states (at level T in Fig. 9). When going from T to $T-\Delta T$, the free-energy valleys subdivide into smaller ones, separated by new barriers (level $T-\Delta T$ in Fig. 9). Rejuvenation arises from the transitions that are now needed to equilibrate the population rates of the new sub-valleys: this is a new aging stage. For large enough ΔT (and in the limited experimental time window), the transitions can only take place between the sub-valleys inside the main valleys, in such a way that the population rates of the main valleys are untouched, keeping the memory of previous aging at T . Hence the memory can be retrieved when re-heating and going back to the T -landscape.

This tree picture allows a qualitative description of the rejuvenation and memory effects, but it is also able to reproduce quantitatively many features of the experiments (see discussions of the effect on aging of small temperature changes in Sasaki et al., 2002; Vincent, 2007). Tree models, starting with Derrida's generalized random energy model (GREM, Derrida and Gardner, 1986) and Bouchaud's trap model (Bouchaud and Dean, 1995), offer a fruitful framework for modelling out-of-equilibrium systems (Hoffmann and Sibani, 1989; Sasaki and Nemoto, 2001). Samarakoon et al. (2017) have investigated memory effects in various magnetic glassy materials (high-temperature superconductors, spin-orbit Mott insulators, frustrated magnets, and a metallic spin glass). They observed memory effects, sharper in the spin glass, less pronounced and closer to a cooling rate effect in other systems. By comparing with a model of random walk on a tree structure, the authors show that the memory effect depends on the hierarchical character of the tree. Recently, Zhang et al. (2021) characterized a disappearance of the glassy behavior and the memory effect above a critical value of tree branching ratio.

The hierarchical scheme in Fig. 9 shows free-energy barriers that are growing as the temperature decreases. The slowing down observed in the dynamics is indeed more drastic than expected from thermally activated dynamics in a fixed landscape. In a series of experiments, the growth of the free-energy barriers upon lowering temperature has been measured (Hammann et al., 1992). The results suggest that some barriers are diverging at all temperatures below T_g , making a link between the hierarchical organization of the metastable states as a function of temperature and that of the pure states in the mean-field spin glass model (a slightly different barrier analysis is presented in Bouchaud et al., 2001).

Let us try to merge into a common framework both views of aging phenomena that we have considered in this discussion:

- a domain growth picture (suggested by the slowing down of the dynamical response during aging), and
- a hierarchical organization of some entities to be defined (suggested by rejuvenation and memory effects).

Fig. 9 Schematic picture of the hierarchical structure of the metastable states as a function of temperature. Fig. 10 Left: Effect of various cooling procedures on the ZFC susceptibility (magnetization divided by field) of the Au: Fe8% spin-glass. Comparison of the effect of fast and slow cooling, with and without stops. Right: difference with the magnetization obtained after fast cooling, emphasizing the memory dips on top of a cooling rate effect.

When large domains have been established during aging at temperature T , with size L_T , rejuvenation at $T-\Delta T$ implies that new processes take place at $L_{T-\Delta T} < L_T$. In order to ensure the preservation of memory at T , we need $L_{T-\Delta T} < L_T$ together with a freezing of the L_T processes at $T-\Delta T$. This is the “temperature-microscope effect” proposed by (Bouchaud et al., 2001). In experiments like those from Figs. 7, 8 and 10, at each temperature stop aging should take place at well-separated length scales $L_n < \dots < L_2 < L_1$, as if the magnification of the microscope were strongly varied at each temperature step.

This “hierarchy of embedded length scales” as a function of temperature is a real space equivalent of the hierarchy of metastable states in the configuration space (Fig. 9). In such a scheme, the domains are not compact, they are embedded cooperative entities in which the spins are correlated up to a characteristic length, which varies quickly with temperature (the crucial point for memory is that the characteristic times increase quickly with decreasing temperature). Later below, in Section “A correlation length for spin-glass order,” we describe experiments in which the correlation length of the spin-glass order can be measured, which bring more information about these embedded length scales.

An experiment gathering the various aspects of aging

We now show an experiment in which cooling rate effects, illustrative of domain-growth processes, can be observed together with memory phenomena.

This is a ZFC-type procedure (*dc*, like in Fig. 1A), proposed by the Uppsala group (Mathieu et al., 2001). The sample is cooled in zero-field with several different thermal procedures, and after applying the field at low temperature the ZFC magnetization is measured while increasing the temperature continuously at fixed speed (small steps of 0.1 K/min).

The results are shown in Fig. 10. Firstly, we can observe the effect of a slow cooling in comparison with that of a fast cooling: the ZFC-curve obtained after a slow cooling lies below the one obtained after a fast cooling. That is, after a slower cooling, the response to the application of the field at low temperature is weaker, the spin-glass state has been more robustly established: the growth of spin-glass ordered domains has been favored by the slower cooling.

Secondly, memory effects can also be observed in this experiment, using now a procedure in which the cooling is interrupted at several temperatures during a one hour waiting time (like in the χ'' experiment in Fig. 8). The magnetization measured during re-heating after this step-cooling procedure shows clear dips at all temperatures at which the sample has been aging. These effects are emphasized in the right part of Fig. 10 where we have plotted the difference between the curves obtained after a specific cooling history and the reference one obtained after a fast cooling. Sharp oscillations (memory dips) show up on top of a wide bump (cooling rate effect).

We may wonder whether the structural glasses, usually considered to be dominated by cooling rate effects, also present rejuvenation and memory phenomena. Experiments have been designed to search for such effects in various glassy systems (including polymers, gels...). They have indeed identified comparable phenomena, although usually less marked than in spin glasses (e.g. Bellon et al., 2002; see references in Vincent and Dupuis, 2018). In simulations of polydisperse repulsive particles, Scalliet and Berthier (2019) have shown that rejuvenation and memory effects are found for packing fractions corresponding to soft colloids and granular materials, whereas such effects are not seen in the regime describing dense supercooled liquids like structural glasses.

An interesting example concerns the mechanical properties of gelatine (Parker and Normand, 2010). Gelatine is a complex protein made of folded helices, and it has many degrees of freedom related to helix unfolding in the vicinity of room temperature. The experiment that we show in Fig. 11 is an *ac* measurement of the elastic modulus G' , it can be compared with the *ac* experiment on a spin glass in Fig. 8. G' has first been measured during simple cooling and re-heating (dashed line, reference). Another measurement has been performed with two stops at two different temperatures during cooling (solid line). During each stop, G' relaxes upwards (the gelatine stiffens, this is aging), and upon further cooling some rejuvenation can be seen. When re-heating, G' shows a dip at each of both stop temperature, the two memory dips are overlapping, but they can be clearly distinguished.

Fig. 11 Measurement of the elastic modulus G' of a gelatine gel, showing aging and memory effects during temperature cycles. Two stops of 2 h were made at 25 and 15 °C during cooling. The left part (A) shows G' as a function of temperature, in solid line for the cycle with stops, and in dashed line for a cycle without stops. During the stops, G' increases slowly (aging). Upon re-heating, a widespread excess of G' is seen when compared with the curve obtained without stops. In the right part (B) of the figure, which shows the difference plot, the memory of both stops shows up clearly. From Parker A and Normand V (2010) Glassy dynamics of gelatin gels. *Soft Matter* 6: 4916–4919.

A correlation length for spin-glass order

The spin-glass order made measurable

It is not obvious to observe the spin-glass ordered domains, since these correlated entities do not present any macroscopic symmetry. Still, the existence of correlated domains separated by frustrated regions has already been mentioned (“clusters”) in early studies of the $\pm J$ spin-glass model (Miyashita and Suzuki, 1981), and small scale simulations allowed the visualization of some long-living domains by studying the spin autocorrelation function (Takano and Miyashita, 1995). Also, in their simulations of the Heisenberg spin glass, Berthier and Young (2004) studied the relative orientations of the spins in two copies (“replicas”) of the system which, starting from different random states, evolve independently by a Monte-Carlo algorithm. Regions of the sample where the spins have a constant angle between both replicas can be rather clearly distinguished. These replica-correlated regions are in a sense equivalent to spin-glass ordered domains, and their growth as a function of time is visible (Fig. 5 in Berthier and Young, 2004).

Yet, it is a challenge to observe these domains in real spin-glass materials. Starting from an idea of R. Orbach, experiments could be developed which allow the measurement of the correlation length of growing domains during aging (Joh et al., 1999). Until this point, we presented experiments which were performed at very low magnetic field, i.e. in which the field is probing but not influencing the spin-glass state (as explained in Section “Slow dynamics and aging in spin glasses”). When using higher amplitudes of the field, we observed that the magnetization relaxation following a field change becomes faster (this can be seen as well in TRM as in ZFC procedures).

The TRM-relaxation curves can be characterized by their inflection point, t_i , which at low field takes place at $t_i \approx t_w$ (TRM curves in Fig. 3). According to thermally activated dynamics, the time t_i defines a typical free-energy barrier U that can be overcome at temperature T after a time t_i (with an attempt time $\tau_0 \approx 10^{-12}$ s defined by the paramagnetic fluctuations):

$$U(t_i) = k_B T \ln(t_i/\tau_0). \quad (11)$$

For a low field TRM relaxation as in Fig. 3, $t_i \approx t_w$, but for higher field amplitudes the relaxation is accelerated and the inflection point t_i shifts toward shorter times (Joh et al., 1999, 2000). Hence, as the field increases, the characteristic barrier $U(t_i)$ decreases (t_i becomes smaller than t_w). We ascribe this energy decrease $U(t_w) - U(t_i)$ to the increase with the field of the Zeeman energy E_Z which couples the magnetic field to the spins. In terms of spin-glass ordered domains involving a typical number of correlated spins N_s with total magnetization M , $E_Z = M \cdot \mu_0 \cdot H$ (here, M is an extensive quantity, not per unit volume as is M in the rest of the paper; μ_0 is the magnetic permeability of vacuum). A natural hypothesis is $M \propto N_s$, but for small numbers $M \propto N_s^{1/2}$ (typical fluctuation for N_s randomly aligned spins) has also been considered (Bert et al., 2004). The recent comparisons of experiments and simulations now offer a better understanding of this question (Zhai et al., 2020; Paga et al., 2021). Let us simply consider here $M \propto N_s$.

For TRM experiments at a given t_w , measuring the field dependence of the inflection point of the curves allows the determination of $N_s(t_w)$. Repeating the measurements for various t_w values yields the time variation of N_s . Fig. 12 shows results obtained from different spin-glass samples (Joh et al., 1999, 2000; Bert et al., 2004).

In this plot, the results from 3 samples do all fall on the same line. The number of correlated spins is, as expected, an increasing function of t_w , reaching during the experiments 10^4 – 10^6 , which means a range of 10–100 lattice units for the correlation length (considering crudely that the size L goes like $N^{1/3}$). The 3 samples have a common behavior which is well fitted by a unique straight line, the solid line in the graph is a power law dependence $N_s = (t_w/\tau_0)^{0.45/T/g}$.

Fig. 12 Number of correlated spins extracted from field change experiments, as a function of the reduced variable $T/T_g \ln(t_w/\tau_0)$. The points with error bars correspond to Heisenberg-like spin-glasses, they are well fitted by the straight line $N_s \sim (t_w/\tau_0)^{0.457/T_g}$. The full circles lying below the others are from the $\text{Fe}_{0.5}\text{Mn}_{0.5}\text{TiO}_3$ Ising sample and call for a more detailed discussion (Bert et al., 2004; Paga et al., 2021). From Joh YG, Orbach R, Wood JJ, Hammann J, and Vincent E (1999) Extraction of the spin glass correlation length. *Physical Review Letters* 82: 438–441; Joh YG, Orbach R, Wood GG, Hammann J, and Vincent E (2000) Finite size effects on spin glass dynamics. *Journal of the Physical Society of Japan* 69 Suppl. A: 215–222; Bert F, Dupuis V, Vincent E, Hammann J, and Bouchaud J-P (2004) Spin anisotropy and slow dynamics in spin glasses. *Physical Review Letters* 92: 167203.

Extrapolating this dependence to $T = T_g$ allows a connection with the dynamic scaling hypothesis $\tau \propto \xi^z$ (Eq. 4). Taking $N_s \propto \xi^3$ yields $z = 1/0.15 = 6.7$, in fair agreement with the dynamic scaling fits to the results of *ac* measurements. Recent experiments on a single crystal of the CuMn spin glass very close to T_g ($T/T_g = 0.9$) have allowed reaching still larger values of the correlation length, up to 240 lattice units (≈ 150 nm), almost at the macroscopic scale (Zhai et al., 2019).

Also, experiments on spin-glass thin films have further investigated the relevance of the spin-glass correlation length. When the correlation length reaches the thickness of the sample, modifications of the rejuvenation and memory effects are seen (Ge:Mn layers of 15.5 nm, Guchhait and Orbach, 2015), and a crossover from 3d to 2d behavior is observed (CuMn layers of 5–20 nm, Zhai et al., 2017).

Let us mention that, in experiments exploring the glassy state formed by interacting magnetic nanoparticles, other data in the intermediate time range have been obtained (Nakamae et al., 2012, and references therein). The microscopic flip time of the *superspins* born by the nanoparticles (10^4 – 10^6 ferromagnetically coupled spins in each nanoparticle) is much longer than 10^{-12} s, ranging up to milliseconds, in such a way that in τ_0 units the explored times are closer to those in simulations. The data from superspins are in continuity with those from spins in both experiments and simulations.

A bridge between experiments and simulations

The numerical simulations of the Edwards-Anderson model (Eq. 1) allow the exploration of the microscopic organization of the spins, which remains inaccessible to the experiments. But an important difficulty is that, due to frustration, the evolution toward equilibrium is very slow, implying time consuming computations. The experiments on real spin glasses are typically exploring the 10^0 – 10^5 s time range, which in units of the paramagnetic spin flip time $\tau_0 \approx 10^{-12}$ s corresponds to 10^{12} – 10^{17} τ_0 . Taking $\tau_0 = 1$ Monte-Carlo (MC) step for comparison, the first numerical simulations were exploring up to $\approx 10^7$ MC steps, a rather short-time regime compared with the experiments (Berthier and Young, 2005). In the Janus and Janus II projects, dedicated supercomputers have been built, which allow computation up to $\approx 10^{11}$ MC steps and more.

In simulations, the correlation length has first been determined from a 4-point correlation function (Marinari et al., 1996), which is not directly related to that measured in the above experiments. In a later stage, it has become possible to fully simulate the experimental procedure in which the correlation length is extracted from the effect of the field on the speed of the magnetization relaxation (method used in Fig. 12). Values of the correlation length up to 17 lattice units could be reached (Baity-Jesi et al., 2018). Since the same method can be used in both experiments and simulations, very interesting comparisons can now be made (Zhai et al., 2019), recently yielding to common publications by experimentalists and theoreticians (Zhai et al., 2020; Paga et al., 2021). Some discrepancies have been found for large applied fields or close to T_g , but a coherent overall description of the results could be reached by defining appropriate scaling laws. The successful modelling of important experimental features of real spin glasses is a crucial progress for a better understanding of complex systems in general.

There has already been an active search for rejuvenation and memory effects in numerical simulations of the Edwards-Anderson model. For Ising spins, they were initially found in $d = 4$, but not in $d = 3$ (Berthier and Bouchaud, 2002, and references therein). For Heisenberg spins, which imply still longer computation times, rejuvenation and memory effects have been seen, but the comparison of the correlation growth in Ising and Heisenberg systems goes at variance between simulations (Berthier and Young, 2005) and experiments (Bert et al., 2004), so the situation is not fully clear. It is likely that the correlation lengths L_{T-AT} , L_T (Section “Domain growth and hierarchy of states”) which could be reached by simulations at different temperatures were not spread

enough to allow $L_{T-AT} < L_T$ and a clear characterization of rejuvenation and memory effects. More space is needed for a full hierarchy of embedded lengths to be at play. Very recently, at the time when this article is being completed, the Janus collaboration could overcome this fundamental hurdle, and succeed in observing rejuvenation and memory effects in the simulated relaxation of the ZFC magnetization (Baity-Jesi et al., 2022).

Temperature chaos is an issue that deserves a new light. It has long been considered as a possible key to rejuvenation (Jönsson et al., 2004), which is a dynamical effect, whereas temperature chaos has been defined in an equilibrium context (Bray and Moore, 1987). Also, it should allow the existence of memory despite rejuvenation. In both Ising and Heisenberg early simulations, the authors indicated that they found no sign of temperature chaos. In the recent large-scale simulations ($L = 160$) by the Janus collaboration, some first signs of a dynamic temperature-chaos effect have been found (Baity-Jesi et al., 2021). In their most recent results, chaos could be clearly characterized, and related with the occurrence of rejuvenation effects (Baity-Jesi et al., 2022).

Conclusion

Within the wide class of disordered materials, spin glasses occupy a special place because of their conceptually simple definition of randomly interacting spins. Spin glasses are disordered magnetic materials which all share a number of common properties, laying down the definition of a generic spin glass behavior.

The spin glass state develops below a well-defined temperature T_g , above which the spins are in paramagnetic state. At T_g , the transition to the spin-glass state presents the same features as for a thermodynamic phase transition to an ordered state, but no macroscopic spin alignment can be seen like in ferromagnets or antiferromagnets. The spin-glass order has a mysterious hidden symmetry, corresponding to spin configurations minimizing the spin-spin interaction energies, which have randomly distributed values.

At T_g , a frozen state is established, but this state is not at equilibrium, it is not totally frozen. After cooling from the paramagnetic phase, starting from a random configuration, the spin-glass order is progressively establishing at longer and longer range, causing aging phenomena that show up in the measured magnetic properties. The characteristic size of the growing cooperative regions has been determined in specific experiments, defining a correlation length for the spin-glass order. Recent developments of numerical simulations, taking benefit of powerful custom-built supercomputers, allow very interesting comparisons of this correlation length of a hidden order in real spin glasses and in the conceptually simple (although highly non-trivial) theoretical models (Paga et al., 2021). A better understanding of these models has important consequences, because they are now part of a tool kit of statistical physics which is used for a wide variety of “complex system” problems, such as econophysics, biology, data compressing, optimization etc.

No simple way has been found to bring a real spin glass closer to an equilibrium state, whose nature is still debated (is it unique, or multiple?). A slower cooling may help partly, as can be efficiently done for structural glasses, but as the temperature is lowered new processes need to be equilibrated, and rejuvenation phenomena show up. Yet, the memory of previous aging states prepared during the cooling can be retrieved upon re-heating. The ability of a spin glass to store several memories of aging at different temperatures is astonishing. A detailed microscopic understanding of the rejuvenation and memory effects at the scale of spin configurations is still lacking. The forthcoming numerical simulations of spin-glass models will probably allow exploring the hierarchy of embedded correlation lengths that is thought to be necessary to observe rejuvenation effects while keeping memory.

In structural and polymer glasses, the dominant scenario is the continuation of aging from one temperature to another. Still, using appropriate procedures, some rejuvenation and memory processes could often be found (as we showed in the case of gelatin). Structural glasses may pertain to a slightly different class of models (spin glass with p-spin interactions, 1-step RSB model, Bouchaud et al., 1996), in which no hierarchy of pure states is found. What are the necessary features of a model in order to obtain rejuvenation and memory phenomena? This has not yet become fully clear. It is an exciting and important challenge to develop a common understanding of glassy systems, and the spin-glass models clearly have a powerful potential in this direction.

On the side of the experiments on real spin glasses, more and more accurate and refined measurements bring a lot of new information (e.g. Zhai et al., 2022). Anomalous Hall effect measurements bring in principle a direct access to spin-chirality freezing (Kawamura, 1992); if they could be pursued, they should shed some light on the nature of the spin-glass transition for Heisenberg spins (Pureur et al., 2004; Taniguchi, 2007). However, one may consider that, for making a significant breakthrough in the understanding of real spin glasses, it is necessary to find some way to access to spin configurations. The key may lie in the study of mesoscopic samples (difficult, due to weak signals), in which the growing correlation length may hit the sample size or a “chaos length” (as for the thin layers in Guchhait and Orbach, 2015, Zhai et al., 2017). Transport measurements on mesoscopic wires may offer some insight in the spin configurations by the universal conductance fluctuations (Carpentier and Orignac, 2008), and provide new perspectives on the spin-glass transition (Forestier et al., 2020).

Acknowledgments

The author deeply thanks V. Dupuis and F. Ladieu for their detailed re-reading of the manuscript and highly relevant suggestions. He also benefitted a lot from very helpful discussions with T. Chakraborty, H. Kawamura, E. Marinari, S. Miyashita and S. Nakamae. H. Bouchiat and A. Parker are warmly thanked for the permission to reuse their figures.

Abstract

Ferroic glass, a concept coined recently, refers to a generic class of frozen disordered ferroic (=ferroelastic, ferroelectric, ferromagnetic) materials with short-range ferroic order; the short-range ferroic order manifests itself as nano-sized ferroic domains which engender from a ferroic glass transition. Ferroic glasses include strain glass in ferroelastic/martensitic systems, relaxor in ferroelectric systems, and cluster spin glass in magnetic systems. They contrast with “ferroic crystals” (i.e., ferroelastics/martensite, ferroelectrics, and ferromagnets), which are characterized by long-range ferroic order or large ferroic domains (mostly micrometer-size) formed by a thermodynamic ferroic transition. The unique short-range order nature of ferroic glasses endows them with technologically important properties not possessed by the corresponding ferroic crystals, such as shape memory and superelasticity in non-martensitic alloys, zero linear thermal expansion (linear Invar effect) and temperature-independent elastic modulus (Elinvar effect), temperature insensitive quasi-linear superelasticity, large dielectric permittivity and electrostrain over wide temperature range, highly sensitive magnetostriction. Ferroic glasses are also found to be the key to understanding a number of longstanding puzzles in ferroic crystals, such as the origin of isothermal martensitic transformation. In this article we overview the state-of-the-arts of ferroic glass research, and present their classification, physical origin, key signatures, novel properties and potential applications in a way understandable to non-specialists. Emphasis is put on the recently-discovered strain glass and physical parallelism among three types of ferroic glasses.

Key points

- Ferroic glasses are a unique class of ferroic (=ferroelastic, ferroelectric, ferromagnetic) materials that have no long-range ferroic order but have frozen short-range ferroic order.
- Ferroic glasses include strain glass in ferroelastic/martensitic systems, relaxor in ferroelectric systems, and cluster spin glass in magnetic systems, and they are physically parallel to one another.
- The unique short-range order nature of ferroic glasses endows them with technologically important properties such as shape memory and superelasticity in non-martensitic alloys, zero linear-thermal expansion (linear Invar effect) and temperature-independent elastic modulus (Elinvar effect), temperature insensitive quasi-linear superelasticity, large dielectric permittivity and electrostrain over wide temperature range, highly sensitive magnetostriction, etc.

Introduction to ferroic glasses

Definition, classification of ferroic glasses, and their physical nature

Ferroic glass is an emerging research area in materials science and physics. The concept was first proposed in 2007 (Wang et al., 2007) and coined recently (Ren, 2014; Ji et al., 2017; Lookman and Ren, 2018). It refers to a frozen disordered form of ferroic (=ferroelastic, ferroelectric, ferromagnetic) materials with frozen short-range order (SRO) manifested microstructurally by nano-sized ferroic domains, as illustrated in Fig. 1a. They include strain glass, relaxor, and cluster spin glass, which exist in ferroelastic, ferroelectric, and magnetic systems, respectively (Ren, 2014). Ferroic glasses contrast with the long-range ordered (LRO) or “crystal” form of ferroic materials (i.e., ferroelastics/martensites, ferroelectrics, and ferromagnets), the latter being characterized microstructurally by large ferroic domains (usually micrometer-sized) (Fig. 1b). The relation between a ferroic glass and a ferroic crystal is analogous to that between an amorphous glass and a crystal. An amorphous glass is a frozen and structurally disordered state with frozen short-range structural order, and a crystal is a structurally long-range-ordered state with the same crystal structure spanning the whole crystalline grain (usually micrometer-size). A ferroic glass has a similar physical picture with an amorphous glass but with a difference in that a ferroic glass is structurally ordered phase (i.e., a crystal) and its frozen disorder or SRO lies in its ferroic order parameter; i.e., lattice strain, ferroelectric dipole, and magnetic moment (Ren, 2014). This is why it is called ferroic glass. As can be expected, the fundamental difference between the glass and the crystal form of ferroic materials can endow ferroic glasses with novel properties not seen in ferroic crystals.

Ferroic glasses can be classified into three subsets according to their microstructural features (Fig. 1a): (i) canonical ferroic glass which is characterized by ferroic nanodomains (SRO only) (Fig. 1a(1)), (ii) crossover ferroic glass which is a composite composed of both ferroic nanodomains and large ferroic domains (a mixture of SRO and LRO or a crossover state from SRO to LRO) (Fig. 1a(2)), and (iii) re-entrant ferroic glass which is characterized by ferroic nanodomains embedded in large ferroic domains of a different ferroic order (SRO embedded in LRO) (Fig. 1a(3)). It is noted that subset (ii) and (iii) contain LRO, and thus are not “canonical ferroic glass”; but they still exhibit glass features despite the existence of LRO. As will be shown later, these non-canonical ferroic glasses are responsible for a number of interesting properties not possessed by canonical ferroic glasses.

Table 1 lists the three subsets of ferroic glasses in ferroelastic/martensitic, ferroelectric, and ferromagnetic systems, respectively. Besides these subsets, there could also exist multi-ferroic glasses which possess two or more kinds of ferroic order with at least one

Fig. 1 Microstructural feature of (a) ferroic glasses (with frozen ferroic SRO) and (b) ferroic crystal (LRO only). Three types of ferroic glasses are shown in (a) according to the relation between SRO and LRO: (1) canonical ferroic glass (SRO only), (2) crossover ferroic glass (a mixture of SRO and LRO), and (3) re-entrant ferroic glass (SRO embedded in LRO of a different ferroic order). Nanodomains with an arrow represent a different ferroic order as those without the arrow. LRO domains of different color represent different domain states.

Table 1 Subsets of ferroic glasses in ferroelastic, ferroelectric, and ferromagnetic materials based on microstructural features.

	<i>Ferroelastic order (strain)</i>	<i>Ferroelectric order (polarization)</i>	<i>Ferromagnetic order (magnetic moment)</i>
Canonical ferroic glass	Strain glass	Relaxor	Cluster spin glass
Crossover ferroic glass	Crossover strain glass	Crossover relaxor	Crossover cluster spin glass
Re-entrant ferroic glass	Re-entrant strain glass	Re-entrant relaxor	Re-entrant cluster spin glass

ferroic order being frozen short-range. For example, ferromagnetic strain glass (to be discussed in Section “Ferromagnetic strain glass: A multi-ferroic glass showing large magnetostriction at a small magnetic field”) belongs to this category, as it possesses long-range magnetic order while demonstrating nano-sized strain domains. As will be seen in Section “Novel properties and potential applications of ferroic glasses,” these different types of ferroic glasses can provide a wide range of novel properties of technological importance.

Being similar with the case of an amorphous glass, ferroic glasses are non-equilibrium states because a disordered or high-entropy glass state is not favored at low temperature according to the 3rd law of thermodynamics, which stipulates that the stable state of any substance should be one possessing zero entropy at 0 K. This universal thermodynamic requirement is the origin of almost all phase transitions, such as the familiar gas-liquid-crystal transition. For ferroic systems the thermodynamically favored state at low temperature is the ferroic crystal because it has long-range order and thus lower entropy. Then an interesting question arises why and how a ferroic glass can form despite its thermodynamic disadvantage as compared with the corresponding ferroic crystal counterpart. The answer to this question will be given in Section “Origin of ferroic glasses and theoretical models.”

History of ferroic glasses

Historically, glass phenomena in three kinds of ferroic systems were discovered independently in three different communities at different period of time (Fig. 2). Relaxor and spin glass have been known from 1960 to 70s in ferroelectric and magnetic communities, respectively; but their counterpart glass in ferroelastic/martensitic materials had remained missing for nearly half a century. With the discovery of the strain glass by Sarkar et al. (2005) in a ferroelastic/martensitic system Ti-Ni, perfect physical parallelism was revealed among three types of ferroic glasses and the concept “ferroic glass” was suggested by Wang et al. (2007). This terminology was coined recently with the publication of several review papers and Springer books (Ren, 2014; Ji et al., 2017; Lookman and Ren, 2018), together with the increasing research activities in international research communities (Monroe et al., 2015; Sun et al., 2020; Xu et al., 2021; Kong et al., 2022; Huang et al., 2020).

In ferroelectric community, it has been found since 1960s that the sharp and frequency-independent permittivity peak at a normal ferroelectric transition is often changed into a broad and frequency-dependent peak by heavy doping. As this phenomenon is similar with the dielectric relaxation phenomenon and it was named “relaxor” (Smolenskii and Agranovskaya, 1960). Although it was realized later that the “relaxor” is not caused by a dielectric relaxation but by a glass transition of ferroelectric order (Bokov and Ye, 2006), it was too late to change this familiar terminology and thus we shall still use it in the present article. In fact, it would be more appropriate to use “polarization glass” instead of “relaxor,” as the former reflects its glass nature and matches the corresponding terminology in other two types of ferroic glasses: strain glass and cluster spin glass.

In magnetic community, it has long been known the existence of a “dirty magnetism,” i.e., many magnetic systems do not show a normal Curie-Weiss peak at their magnetic transition; Instead, they show a frequency-dependent susceptibility cusp, and ferromagnetism is absent even down to 0 K. This phenomenon was named “spin glass” transition in early 1970s (Cannella and Mydosh, 1972). In the spin glass literature, spin glass is conceptually subdivided into two subsets: a “dilute spin glass” with nearly isolated and disordered spins being frozen, and a “cluster spin glass” with frozen nano-sized ferromagnetic domains or clusters (Mydosh, 1993), although a clear-cut difference in the experimental signatures does not seem to exist. In the present article, we shall confine our discussion to cluster spin glass when mentioning spin glass, as it is physically parallel to strain glass and relaxor, both being cluster glasses. For a detailed discussion of spin glass and the related experiments, readers may refer to the article by Vincent (2022) in this edition of Encyclopedia.

In ferroelastic/martensitic community, although the long-range ordered form of strain order, known as martensite or ferroelastic, has been known for more than one century and some of these materials like martensitic steels and shape memory alloys have found wide applications, the glass form of strain order, i.e., strain glass, has not been discovered until 2005 (Sarkar et al., 2005). It was

Fig. 2 Historical development of relaxor, spin glass, strain glass, and the advent of the concept “ferroic glass” (Ren, 2014). The three insets show a universal feature of ferroic glass transition, the frequency-dependence of susceptibility peak vs. temperature, where T is temperature, ϵ , χ' , χ'' , E are dielectric, magnetic, and mechanical susceptibility, respectively, and E is elastic modulus.

found that strain glass is characterized by a frequency-dependency peak in the elastic susceptibility (the inverse of elastic modulus), which very much resembles that of a relaxor and a cluster spin glass, as shown in the insets of Fig. 2.

It should be noted that before the experimental discovery of strain glass transition in 2005 (Sarkar et al., 2005), there had existed some theoretical effort to use “spin-glass-like models” to understand “premartensitic tweed” phenomenon that occurs prior to the onset of a martensitic transition (Kartha et al., 1991; Semenovskaya and Khachatryan, 1997). These models predicted a glassy transition in the premartensitic state but they did not gain experimental confirmation (Ren et al., 2010). Now it becomes clear that the premartensitic state is not yet a frozen strain glass state.

The discovery of strain glass completed the physical parallelism among three types of glasses in three ferroic systems. Therefore, a generalized concept “ferroic glass” was suggested (Wang et al., 2007), which means a frozen state of certain ferroic order (Ren, 2014; Ji et al., 2017; Lookman and Ren, 2018). This concept enables a unified understanding of glass phenomena in three types of ferroic systems (see Section “Origin of ferroic glasses and theoretical models”).

Generic phase diagram of a ferroic glass system: Link between ferroic LRO and ferroic frozen SRO

Fig. 3a show the generic phase diagram of a ferroic glass (Ren et al., 2010), which captures the common features of phase diagrams in strain glass (Sarkar et al., 2005), relaxor (Sun et al., 2013) and cluster spin glass systems (Wang et al., 2015) (Fig. 3b–d). Such phase diagrams are essential to understand ferroic glasses as they reveal the relationship among all possible ferroic states in a ferroic system. These states include para-phase (“ferroic liquid”), ferroic crystal (long-range ferroic order), unfrozen ferroic glass (a sticky to less-sticky ferroic liquid, or precursory tweed), and ferroic glass (frozen short-range ferroic order) as shown in Fig. 3a. A crossover from ferroic transition (at T_c) to ferroic glass transition (at T_g) occurs when defect (dopant) concentration x exceeds a critical value x_c . Note that in the crossover region, the ferroic glass can transform into the ferroic crystal upon cooling or by applying an external field, and such a transition is called spontaneous or field-induced transition from ferroic glass to ferroic crystal. It is physically analogous to the crystallization transition of an amorphous glass. This crossover region corresponds to the ferroic glass subset “crossover ferroic glass” shown in Fig. 1(a2).

The striking similarity in phase diagram among the three different types of ferroic glasses suggests a common physical nature for all ferroic glasses. The phase diagrams also suggest that a ferroic glass state is derived from a ferroic crystal state by introducing sufficient defects (dopants). This important feature of ferroic glass imposes an important constraint to possible ferroic glass theories: a correct theory must explain the crossover from a ferroic crystal state to a ferroic glass state by defects.

Origin of ferroic glasses and theoretical models

The 3rd law of thermodynamics stipulates that all substances should take an ordered form at 0 K so as to ensure zero entropy. This thermodynamic requirement is the origin of almost all phase transitions including gas-liquid-crystal transition, and ferroic transitions from a para (ferroic liquid) state into a long-range ordered ferroic crystal state (i.e., ferroelastic/martensite, ferroelectric, and ferromagnetic state), because these transitions result in long-range ordering of ferroic order and consequently reduce entropy.

However, a ferroic glass seems at variance with the above general picture, since its frozen ferroic disordered state is a high entropy state that can persist down to 0 K; thus it is against the thermodynamic requirement of zero entropy at 0 K. Therefore, the formation of a ferroic glass, i.e., ferroic glass transition, is not a conventional thermodynamic transition and its origin needs explanation.

A cartoon illustrated in Fig. 4a and b schematically shows the origin of a normal ferroic transition (i.e., LRO) and that of a ferroic glass by using a domino array without and with “stone disturbance.” It can be seen easily that a pure ferroic system (without “stones”) will undergo a normal ferroic transition with long-range ferroic ordering, as required by thermodynamics. However, when a ferroic system is doped with many defects (many “stones”), it becomes impossible to form a long-range ordered ferroic phase due to the disturbance of the randomly distributed defects; instead, the system is frozen into a disordered state with short-range ferroic order only. Therefore, ferroic glass and ferroic glass transition originate from random defects that produce “random field” and thus

Fig. 3 (a) Generic phase diagram of a ferroic glass with all possible ferroic states shown (generalized from Ren et al., 2010). (b) Experimental phase diagram of a strain glass system $\text{Ti}_{50-x}\text{Ni}_x$, the insets being microstructural features of different strain states (Sarkar et al., 2005). (c) Experimental phase diagram of a relaxor system $\text{Pb}_{1-x/100}\text{La}_{x/100}(\text{Zr}_{0.4}\text{Ti}_{0.6})_{1-x/400}\text{O}_3$ (Sun et al., 2013). (d) Experimental phase diagram of a cluster spin glass system $\text{Ni}_{1-x}\text{V}_x$ (Wang et al., 2015).

Fig. 4 A cartoon showing the origin of (a) ferroic crystal and (b) ferroic glass and its relation to random defects (represented by “stone”) (Ren, 2014). Here a strain system is taken as an example but the generic picture applies to magnetic and polar systems. P denotes the parent phase or strain liquid state; M represents the martensitic phase or strain crystal; the “stones” in (b) represent defects or dopants, and STG represents strain glass state or frozen local strain state.

prohibit the formation of long-range ferroic ordering, or a ferroic crystal. Instead, a ferroic glass (a frozen short-range ordered ferroic state) is formed, and such a metastable state can persist down to 0 K.

Rigorous phase field models reflecting the above physical picture have been developed for strain glass (Wang et al., 2010) and for relaxor (Wang et al., 2012; Hong et al., 2022), and a similar phase field theory is expected for cluster spin glass but is lacking so far. The kernel of these phase-field models is a Landau-Ginzburg free energy that favors a normal ferroic crystal transition, and random field caused by defects that tend to destroy the long-range ferroic order. The competition between the two effects creates a crossover from a normal ferroic transition into ferroic glass transition when defect concentration is beyond a critical value. Therefore, these models provide a reasonable explanation for the most important fact about ferroic glasses: the existence of a crossover from ferroic crystal to ferroic glass by defect doping, as shown in Fig. 3.

Examples of the calculated phase diagrams of a strain glass and a relaxor, together with the evolution of ferroic microstructure with defect doping level and temperature, are shown in Fig. 5a–d, respectively (Wang et al., 2010, 2012). The calculated phase diagrams (Fig. 5c and d) and microstructure features (Fig. 5a and b) are in qualitative agreement with the experimental phase diagrams and microstructures shown in Fig. 3. The theories also reproduce all other signatures of ferroic glasses as shown in the next section.

It is noted that alternative theories about ferroic glasses have been proposed (Lloberas et al., 2008, 2009; Sherrington, 2008, 2014; Vasseur and Lookman, 2010), and interested readers can refer to these references for details.

Signatures of a ferroic glass or a ferroic glass transition

As ferroic glass is formed through a ferroic glass transition, the signatures of a ferroic glass are also those of a ferroic glass transition. The key experimental signatures of a ferroic glass transition or a ferroic glass are given below (Ren, 2014, 2012; Ji et al., 2017; Lookman and Ren, 2018).

(i) Absence of a ferroic crystal transformation (Fig. 6)

As a ferroic glass is formed via a freezing transition from a ferroic liquid (para-state) into a frozen disordered state (ferroic glass state), it involves no change in long-range ferroic order or average structure. Therefore, a ferroic glass appears like a non-transforming material and shows no ferroic transition signature when average ferroic order is monitored. Fig. 6 shows an example of a strain glass alloy (Wang et al., 2006), which exhibits an invariance of average structure (=XRD peaks) with temperature, and no thermal hysteresis in resistivity curves. A strain glass also exhibits no latent heat peak in differential scanning calorimetry (DSC) curves (Sarkar et al., 2005), which contrasts the case for a normal ferroelastic transition.

Fig. 5 Phase field simulation results for strain glass (a, c) (Wang et al., 2010), and relaxor (b, d) (Wang et al., 2012): calculated ferroic glass phase diagram and evolution of domain pattern as a function of defect concentration and temperature.

Fig. 6 Invariance of average structure in a strain glass $\text{Ti}_{48.5}\text{Ni}_{51.5}$ alloy (Wang et al., 2006), which has a strain glass transition at $T_g \sim 168$ K. The XRD pattern in the inset shows an average B2 structure over the entire temperature range of strain glass transition. The resistivity curves during cooling and heating show no thermal hysteresis.

(ii) Freezing signature as manifested by dynamic measurement (Fig. 7)

The existence of a ferroic glass transition can be easily seen by measuring its “ferroic stickiness,” i.e., the appearance of a Vogel-Fulcher-type frequency-dependent anomaly in its dynamic ferroic property, which is dynamic mechanical susceptibility/modulus, dielectric permittivity, and magnetic susceptibility for strain glass, relaxor, and cluster spin glass, respectively (Ren, 2014).

Fig. 7a shows that a strain glass transition is characterized by a frequency-dependent peak/dip in the dynamic elastic modulus/loss around its freezing temperature T_g . T_g follows the Vogel-Fulcher relation $\omega = \omega_0 \exp[-E_a/k_B(T_g - T_0)]$, which is a signature of any glass, where T_g is the dip/peak temperature at frequency ω and T_0 the “ideal” freezing temperature (T_g at 0 Hz), E_a is the activation

Fig. 7 Frequency-dependent anomaly associated with (a) a strain glass transition revealed by dynamic mechanical analysis (DMA) (Sarkar et al., 2005), the inset showing schematically the microscopic picture of the strain freezing process, (b) a relaxor transition revealed by dielectric permittivity measurement (Tan et al., 2000), and (c) a cluster-spin glass ($\text{La}_{0.7}\text{Ca}_{0.3}\text{Mn}_{0.8}\text{Co}_{0.2}\text{O}_3$) revealed by magnetic susceptibility measurement (Karmakar et al., 2006).

energy and k_B is the Boltzmann constant. Fig. 7b and 7c show very similar frequency dependent anomaly at T_g exists in other two types of ferroic glasses, relaxor (Tan et al., 2000) and cluster spin glass (Karmakar et al., 2006), respectively.

(iii) Broken ergodicity as signified by branching zero-field-cool/field-cool (ZFC/FC) curves (Fig. 8)

An important signature of a ferroic glass transition is ergodicity-breaking, or history dependence of sample state when entering a glass state. This is usually done with a ZFC/FC experiment, which generates two different histories to the sample. Fig. 8a shows the mechanical ZFC/FC curves of a strain glass $\text{Ti}_{48.5}\text{Ni}_{51.5}$ alloy (Wang et al., 2007). The branching ZFC and FC curves below T_g suggests a broken ergodicity in the strain glass state. Relaxor (Viehland et al., 1992) and cluster spin glass transition (Gayathri et al., 1997) also demonstrate strikingly similar ZFC/FC curves (Fig. 8b and c, respectively), although the driving field (electric and magnetic field here) is different.

(iv) Existence of nano-sized ferroic domains revealing the SRO ferroic ordering nature (Fig. 9)

Although a ferroic glass possesses no LRO (i.e., absence of large ferroic domains), it can show short-range ferroic order down to 0 K. The short-range ferroic order manifests itself as nano-sized ferroic domains, as exemplified in a strain glass (Fig. 9) revealed by *in-situ* high-resolution transmission electron microscopy (HRTEM) observation (Zhou et al., 2014). Similar nanodomains have also been reported in relaxors (Wang et al., 2021), confirming the common SRO nature of this type of ferroic glass. Unfortunately, direct microscopic imaging of magnetic nanodomains in cluster spin glass are scarce, due to the difficulty in high-resolution imaging of nano-sized magnetic domains. Effort towards this direction is much desired.

Novel properties and potential applications of ferroic glasses

Just like amorphous glasses possess many properties unattainable in crystalline materials, ferroic glasses also demonstrate interesting novel properties not achievable in ferroic crystals. Below we give a few examples of recent findings about novel properties of ferroic glasses.

Fig. 10 (a) Shape-memory effect (deformed below T_g) and superelasticity (deformed above T_g) of a $\text{Ti}_{48.5}\text{Ni}_{51.5}$ strain glass alloy. (b, c) Visual evidence for shape-memory effect and superelasticity, respectively. (Wang et al., 2006).

Strain glasses

(i) Shape memory effect and superelasticity in strain glass alloys.

It is a striking surprise when a strain glass is found to exhibit shape memory effect and superelasticity (Fig. 10) (Wang et al., 2006), because such properties are usually associated with an alloy undergoing a spontaneous martensitic transformation but a strain glass does not undergo such martensitic transformation. These unexpected properties arise from a stress-induced strain glass to martensite transformation and its reverse transition. Shape memory effect occurs when a strain glass is deformed below its glass transition T_g (to form martensite) and subsequently warmed up to above T_g (to transform the martensite into unfrozen strain glass). Superelasticity is found when a strain glass is deformed above its glass transition T_g because the stress-induced martensite is thermodynamically unstable and thus recovers the original unfrozen strain glass state upon unloading. The existence of shape memory effect and superelasticity in non-martensitic alloys (i.e., strain glasses) is expected to open a new avenue for the applications of strain glass as a novel class of smart materials.

(ii) Linear Invar effect and Elinvar effect in Ti-based and Mg-based strain glass alloys.

Invar effect refers to dimension invariance with temperature, i.e., zero thermal expansion, and Elinvar effect refers to elastic modulus invariance with temperature. These two effects exist in few alloys and have found important applications in precision instruments but the origin has remained unclear. Over the past decade, these unusual properties were reported in a non-transforming “Gum metal,” a heavily doped Ti-alloy, after severe cold-rolling (Saito et al., 2003). It is interesting to note that the Invar effect in Gum metal exists only along the rolling direction of the sample and thus it can be called “linear Invar effect.” The origin of these interesting properties in the Gum metal had also remained unclear.

Wang et al. (2014) found that the Gum metal is actually a strain glass alloy, and as a consequence the linear Invar effect and Elinvar effect can be explained. The linear Invar effect occurs as a result of length compensation by oriented strain glass nanodomains which offset the ever-present thermal expansion. Elinvar effect occurs as a result of modulus compensation by the appearance of elastically harder strain glass nanodomains which offset the softening matrix.

Very recently Liu et al. (2022) reported that a lightweight Mg-Sc strain glass alloy exhibits Elinvar effect (Fig. 11), and it is the lightest Elinvar alloy reported so far. They showed that this behavior originates from its strain glass nature and the alloy may found applications in space technologies where stable elasticity is required.

(iii) Quasi-linear superelasticity associated with dislocation-induced strain glass.

Differing from the usual case that strain glass is formed by point defect doping, it has been shown by Liang et al. (2017, 2022) that strain glass can also be formed by introducing high density of dislocations into a martensitic alloy. They found that the dislocation-induced strain glass exhibits a “quasi-linear” superelasticity which is stable over a superwide temperature range (Fig. 12). This overcomes the key drawback of conventional superelasticity of shape memory alloys where superelasticity is highly temperature sensitive and vanishes below martensitic transformation temperature. Although the quasi-linear superelastic strain ($\sim 4\%$) is not as large as the conventional non-linear superelasticity in Ti-Ni alloys ($\sim 8\%$), its temperature stability, high strength, relatively low modulus make the dislocation-induced strain glass a promising elastic material.

Fig. 11 Elinvar-type low modulus in a lightweight Mg-Sc strain glass alloy (Liu et al., 2022). It is noted that neither non-transforming Mg-alloys nor martensitic Mg-alloys show the Elinvar behavior.

Fig. 12 (a) Temperature insensitive quasi-linear superelasticity in a dislocation-induced $\text{Ti}_{49.2}\text{Ni}_{50.8}$ strain glass alloy. The alloy experienced cold-rolling by 27% thickness reduction before testing. (b) Stress hysteresis as a function of temperature. (c) Variation of elastic modulus with temperature. (Liang et al., 2017).

In addition to dislocation-induced strain glass mentioned above, Ji et al. (2013) showed that high-density 3D defects of nano-precipitates can also change a martensitic alloy into a strain glass one. Jiang et al. (2021) further showed that high-density grain boundaries in a nanocrystalline TiNiPt alloy can also induce a strain glass transition, and the grain-boundary-induced strain glass exhibits significant superelasticity of 6%. Therefore, it seems that sufficient defects of 0D (point defects), 1D (dislocations), 2D (grain boundaries), and 3D (nano-precipitates) can destroy the long-range order of an otherwise martensitic material, and change it into a strain glass, which is characterized by frozen SRO strain.

Relaxors: achieving high permittivity over a wide temperature range by coexisting relaxor nanodomains

A desired property of ferroelectric materials is achieving high permittivity over a wide temperature range. However, this is impossible for normal ferroelectric materials and normal relaxors. This is because the former has a very high permittivity at T_C but it sharply decreases when temperature deviates from T_C ; on the other hand, relaxor has a broad permittivity peak and thus less temperature sensitive but its permittivity value is much lower than a ferroelectric permittivity peak value.

By adjusting relaxor compositions Yang et al. (2019) were able to design a special relaxor composed of two kinds of different ferroic nanodomains (with rhombohedral and tetragonal local symmetry, respectively), and this special relaxor state in the phase diagram is termed “morphotropic relaxor boundary or MRB,” as shown in Fig. 13. They found that the MRB relaxor can lead to a 1.5 time increase in permittivity and a 3-time increase in electrostrain. In addition, the enhancement effect can persist over a wide temperature range of over 100 K. Further studies on high- T_g MRB systems (Yang et al., 2021; Zhu et al., 2022; Pan et al., 2019; Chen et al., 2023; Xia et al., 2021) confirmed this important effect and showed that large enhancement effect can be achieved at room temperature, a result crucial for the use of this effect in room temperature devices.

Fig. 13 (a) The existence of a morphotropic relaxor boundary (MRB) in the phase diagram of $(K_{0.5}Na_{0.5})NbO_3$ - $BaTiO_3$ relaxor system (Yang et al., 2019). Local probes of convergent beam electron diffraction (CBED) and high-resolution electron microscopy (HREM) provide direct evidence for a composition-induced local symmetry boundary (i.e., MRB). (b) Property enhancement at the MRB composition in comparison with the off-MRB compositions. (b1) (b2) and (b3) are composition dependence of small-field dielectric permittivity (at 10⁴ Hz), high-field dielectric permittivity, and electrostriction at room temperature (298 K). The high-field dielectric permittivity at 50 kV/cm is calculated through the slope of the P-E relation (inset).

Recently, Wang et al. (2021) succeeded in fabricating a “tri-relaxor,” which is a mixture of three kinds of ferroic nanodomains (with rhombohedral, orthorhombic, tetragonal local symmetry, respectively) by engineering a tri-critical quadruple-point ferroelectric into a relaxor state through suitable doping (Fig. 14). They demonstrated that the tri-relaxor possesses an outstanding combination of high permittivity ($\sim 17,000$) with a large temperature span (~ 34 K). Recently He et al. (2021) reported that a large electrostrain with nearly-vanished hysteresis in Bi-doped $Ba(Zr_{0.2}Ti_{0.8})O_3$ - x ($Ba_{0.7}Ca_{0.3}$) TiO_3 ceramics by establishing a “tri-relaxor.” Therefore, both MRB relaxor and tri-relaxor can become important strategies in improving dielectric and electrostrain properties of relaxor materials.

Crossover relaxor: achieving high electrostrain and small hysteresis simultaneously

Fang et al. (2018) designed a unique crossover relaxor in a ferroelectric BT-5Bi-xSn system, as shown in Fig. 15. It is a crossover state between a relaxor and ferroelectric. As microstructurally the crossover relaxor appears as a composite composed of relaxor and ferroelectric, it is called “re-entrant relaxor-ferroelectric composite (RRFC).” The RRFC is found to exhibit an excellent combination of low hysteresis and large electrostrain—usually such a technologically-desired property is difficult to achieve due to the trade-off relation between large strain and small hysteresis. The unique property of RRFC can be understood based on the ferroelectric and relaxor coexisting microstructure.

Dai et al. showed in several ferroelectric/relaxor systems (Dai et al., 2020a,b; Dai et al., 2021; Dai et al., 2022) that by engineering the materials into a ferroelectric/relaxor crossover state, an excellent combination of both high storage density of electric energy (i.e., high permittivity) and good energy storage efficiency (i.e., small hysteresis) is achieved. Such a property has been difficult to obtain for either ferroelectric materials (LRO materials) or relaxor materials (SRO materials), but is essential for electric energy storage by using dielectric materials. Therefore, a ferroelectric/relaxor mixture state may be an effective solution to this demand.

Re-entrant strain glass showing low modulus and high damping

Very recently Wang et al. (2022) discovered a re-entrant strain glass transition in a well-known shape memory alloy $Ti_{50}Ni_{34}Cu_{16}$. The re-entrant strain glass transition is characterized by the gradual formation and freezing of 4H strain glass domains in a B19 martensite matrix (Fig. 16). It differs from a conventional strain glass in that the strain glass nanodomains do not form from a disorder phase (parent phase) but from an ordered matrix (i.e., martensite). The re-entrant strain glass transition stems from Cu

Fig. 14 (a) Large and temperature-insensitive dielectric permittivity of a tri-relaxor as compared with off-tri-relaxor compositions (Wang et al., 2021). (b) Modified Curie-Weiss fitting for $x = 0.12, 0.16$, and 0.19 compositions showing slope parameter $\gamma \rightarrow 2$, which suggests the characteristic of a relaxor. (c) Outstanding permittivity vs. temperature-span benchmark of tri-relaxor as compared with various ferroelectric and relaxor materials. (d1–d3) Temperature-insensitive nanodomain structure of the tri-relaxor.

dopants which stabilize the B19 phase but hinders the formation of long-range 4H martensite phase at low temperature through their random field. As a result, a short-range ordered 4H nanodomains are formed out of the B19 matrix without the formation of 4H martensite.

Interestingly, the re-entrant strain glass transition was found to lead to very low modulus (~ 24 GPa) and high damping ($\tan \delta > 0.075$) over a wide temperature range (> 100 K). This suggests that re-entrant strain glass alloy may be used as low-modulus high-damping alloy.

Very recently, Fang et al. (2023) reported that a re-entrant strain glass transition in a La-doped CaTiO_3 ceramic, which can toughen the brittle ceramic down to cryogenic temperatures, and thus may become a promising strategy to toughen brittle materials.

Ferromagnetic strain glass: A multi-ferroic glass showing large magnetostriction at a small magnetic field

As mentioned at the beginning of this article, a multi-ferroic glass is expected to exist in a system with more than one type of ferroic order. Ren et al. (2017) showed such a multi-ferroic glass does exist in a $\text{Fe}_{67.7}\text{Pd}_{32.3}$ alloy, which is ferromagnetic but undergoes a strain glass transition in the ferromagnetic state. Therefore, the alloy is a ferromagnetic strain glass, a subclass of multi-ferroic glass.

The $\text{Fe}_{67.7}\text{Pd}_{32.3}$ ferromagnetic strain glass overcomes the trade-off relation between large magnetostriction and small hysteresis, which is known for existing ferromagnetic materials (Fig. 17a). It shows a large magnetostriction of 800 ppm at a low critical field of 0.8 kOe (Ren et al., 2017). This desired highly sensitive magnetostriction effect originates from the ferromagnetic strain glass nanodomains being switchable at small magnetic field (Fig. 17b). This discovery suggests that ferromagnetic strain glass could be an effective approach to design extraordinary magnetostrictive materials.

Ferromagnetic strain glasses have also been reported in many other ferromagnetic martensite systems and interesting magnetostrictive properties are also demonstrated (Ma et al., 2015; Khan et al., 2020; Wang et al., 2018).

Fig. 15 Combination of low hysteresis and large strain of the RRFC at room temperature (Fang et al., 2018). (a) Electrostrain of ferroelectric ($x = 4$), RRFC ($x = 7$) and relaxor ($x = 9$), with hard PZT piezoelectric and electrostrictive PMN relaxor being a reference. (b,c) Composition dependence of maximum strain S_{max} and hysteresis under the electric field of 3 kV/mm. (d) TEM images show the corresponding microstructure of typical ferroelectric ($x = 4$), RRFC ($x = 7$), and relaxor ($x = 9$), respectively. The inset is a fast Fourier transform of the image which shows the spot splitting and suggests local ferroelectric order.

(b) Microstructure feature of a re-entrant strain glass above and below its glass transition temperature. (c) Ultralow elastic modulus and high damping over a wide temperature range associated with a re-entrant strain glass transition.

Isothermal “crystallization” of strain glass as the origin of isothermal martensitic transformation

A long-standing puzzle in martensite community since 1930s is the origin of isothermal martensitic transformation—a gradual formation of martensite over a time scale as long as hours and days. For a diffusional transition like water freezing, the time-dependence of the transition is natural because atomic diffusion takes time and it is impossible to complete instantaneously.

Fig. 17 (a) Benchmark of magnetostriction vs. saturation magnetic field H_s for Fe-Pd ferromagnetic strain glass and other typical magnetostrictive materials, “DS” represents directionally solidified alloys, and “PC” stands for polycrystalline alloys. (b) TEM picture of this ferromagnetic strain glass. (Ren et al., 2017).

However, for a diffusionless transition like martensitic transition (as well as other ferroic transitions), the transition can complete at a speed of sound because it involves with a collective displacement/shift of the atoms without needing a time-consuming diffusion process. Therefore, martensitic transformation is usually found to be time-independent but temperature dependent, and thus it is called “athermal” transition, meaning “caused by temperature change.” However, exceptions to this general picture have been reported in a number of martensitic alloys since 1930, but its origin had remained unclear.

By studying a martensitic alloy $\text{Ti}_{48.7}\text{Ni}_{51.3}$ which locates at the strain-glass/martensite crossover composition, Ji et al. (2015) discovered an important clue that can resolve this longstanding puzzle. They found that the “isothermal martensitic transformation” is not a transform from parent phase (a strain disordered phase) into a martensite, as commonly assumed; rather it is a transition from a frozen strain glass (a SRO phase) into a martensite (a LRO phase) (Fig. 18). Therefore, it is a spontaneous

Fig. 18 Spontaneous “crystallization” of a strain glass as the origin of isothermal martensitic transformation (Ji et al., 2015). (a) Temperature monitor of the isothermal aging experiment. (b) Resistivity increase during isothermal aging, which reveals the formation of R-martensite. (c) Time dependence of in situ X-ray diffraction patterns. Additional peaks gradually appear close to $(220)_{B2}$ peak and are determined to be the $(224)_R$ and $(600)_R$, respectively. (d) Simulated microstructure evolution with time through phase field modeling.

“crystallization” of strain glass into a strain crystal—the martensite. Because the growth of nano-sized strain glass domains into large martensite domains takes time, this spontaneous crystallization process is time-dependent. This provides a transparent explanation for the existence of isothermal martensitic transformation and for why such transformation exists only in defect-containing alloys.

A similar study on a relaxor/ferroelectric crossover composition in a PZT-La system shows that an isothermal ferroelectric transition occurs under such a condition (Sun et al., 2013). Therefore, the puzzling isothermal transition in certain ferroic materials originates from the time-dependent crystallization of ferroic glasses into ferroic crystals when composition is located around the glass/crystal crossover of the phase diagram.

Conclusion

In this article we have presented a concise introduction to ferroic glasses, their classifications, physical origin, and experimental signatures, together with their physical properties and potential applications. Ferroic glasses are a unique class of ferroic materials characterized by nano-sized ferroic domains (or frozen SRO) formed through a ferroic glass transition. Just like amorphous glasses being contrasted with crystalline materials with their unique properties, ferroic glasses also exhibit many unique properties not possessed by their ferroic crystal counterparts. Some of these properties have been revealed recently and discussed in this article but more are to be discovered in the future. These novel properties are expected to lead to promising applications. Therefore, ferroic glass is an emerging research field that not only provides a new playground for materials scientists and physicists but also will lead to novel materials for exciting applications.

Abstract

This presentation starts with a general description of the electronic energy structure of insulators. This is the background of basic semiconductor features including the bands and the forbidden gap, the effective mass, the mobility and doping with donors or acceptors. Then, the rectification mechanisms of Schottky barriers and p - n junctions are outlined. The next part is a short presentation of some important semiconducting materials. Finally, optical properties are discussed together with their use for devices.

Key points

- Semiconductors: electronic energy structure
- Bands and gaps
- Effective masses, mobility
- Doping
- Diodes
- Important semiconductors
- Optical devices

Introduction: Insulators and semiconductors

When atoms are connected together by chemical bonds to form solids, their electronic states and energy levels are modified. For insulating materials, the valence electrons occupy “bonding” states whose energies form the “valence band.” Above the valence band there is a “forbidden gap” with no states and then the “conduction band” corresponding to “antibonding” states (Fig. 1a).

At absolute zero temperature, $T = 0$ K, the valence band is completely full and the conduction band completely empty. The electronic states of the valence band are globally symmetric and produce no net electric current.

This situation changes if the temperature is higher than absolute zero (Fig. 1b). Some electrons are thermally promoted above the gap and into the conduction band. An applied voltage can shift them to nearby empty states, breaking the global symmetry and producing a current. This effect is stronger for smaller gaps that allow more electrons to be promoted to the conduction band. In addition, the states left empty in the valence band allow breaking its global symmetry, also contributing to the current when a bias voltage is applied.

[☆]*Change History:* November 2022. G Margaritondo updated all sections and figures.

Fig. 1 (a) The electronic states in an insulator or a semiconductor correspond to a valence band of energies and to a conduction band, separated by a forbidden gap of width E_g . At absolute zero temperature, all valence-band states are occupied and all conduction-band states are empty. (b) At finite temperatures, some electrons are present in the conduction band leaving empty states in the valence band. The state occupation is ruled by the Fermi-Dirac function (plotted here for $T = 0$ K and $T > 0$ K) and in particular by its Fermi level E_F .

The gap width E_g marks the difference between “insulators” and “semiconductors.” Indeed, a semiconductor is an insulator with a sufficiently small gap to allow a significant number of electrons in the conduction band at room temperature. In practice, for most semiconductors E_g does not exceed 2.5–3 eV.

The densities of electrons in the conduction band and of empty states in the valence band are determined by thermodynamic statistics. The electrons are particles with spin 1/2, thus they are ruled by the Fermi-Dirac quantum statistics function—which is a consequence of the Pauli exclusion principle. The function, with occupancy ranging from 0 to 1, is plotted in Fig. 1b.

At absolute zero temperature, the Fermi-Dirac function is a sharp step: the occupation probability is 100% up to the Fermi level E_F and zero above it. Thus, E_F for an insulator or a semiconductor falls within the forbidden gap. At finite temperatures, the Fermi-Dirac function allows some empty states below E_F and some electrons above it.

In a metal, E_F falls in the conduction band rather than in a gap. An applied voltage creates a current by changing the states of electrons close to E_F , with no need to thermally excite them above a forbidden gap. Thus, many more electrons contribute to the electrical conduction in a metal than in a semiconductor. However, a semiconductor has a marked advantage: as we shall see, its properties can be modified and controlled by exploiting mechanisms not active in metals, opening the door to many applications.

As a consequence, semiconductors have become the protagonists of modern electronics. In practice, this is mainly due to three facts: (1) the possibility to control their conduction mechanisms by “doping” them with suitable impurities; (2) the possibility of electrically and chemically passivating their surfaces with high-quality, ultrathin insulating layers, as required to integrate a huge number of microdevices into a single semiconductor slice (the “planar technology” of integrated circuits); (3) properties other than electrical conduction, such as the optical ones, that are controlled and exploited for special devices like visible-light emitters and solar cells.

In order to understand how semiconductor devices work, we must first analyze the basic conduction mechanisms of the materials. We must specifically discover the role of the electrons in the conduction band and of the empty electronic states in the valence-band, described by the so-called “holes.”

Effective mass, electrons, and holes

We shall begin by analyzing an electron not subject to forces, free to move along a straight line, i.e., in one dimension. Its momentum is:

$$mv = p = \hbar k, \quad (1)$$

where m is the mass, v the velocity and k the wave number of the electron wave (which in three-dimensions becomes the $\mathbf{k}$ -vector). And its (kinetic) energy is:

$$E = mv^2/2 = p^2/(2m) = [\hbar^2/(2m)]k^2. \quad (2)$$

Therefore, the “dispersion curve” $E(k)$ is a parabola—see Fig. 2a. Note that:

$$m = \hbar^2 / (d^2E/dk^2), \quad (3)$$

and

$$(1/\hbar)(dE/dk) = (\hbar/m)k = p/m = v \quad (4)$$

Electrons in a crystal

Assume now that the electron is no longer free but subject to a periodic potential caused by the positively charged nuclei in a crystal. We shall perform our analysis again in one dimension, for a potential with period a as shown in Fig. 2b.

Fig. 2 (a) $E(k)$ curve for a free electron. (b) Periodic potential created by the nuclei in a one-dimensional crystal. (c) “Folding” of the $E(k)$ curves into the first Brillouin zone. (d) Deformations of the $E(k)$ curves by the “Bragg reflections,” which create bands and gaps.

The electron behaves as a wave interacting with the nuclei. In turn, the array of nuclei can be seen as a standing wave of positive electric charge with period a . Mathematics show that this standing wave can be expressed as a sum of “propagating waves” moving in opposite directions, with wave number $k = \pm \xi 2\pi/a$ and momentum $\hbar k = \pm \xi 2\pi\hbar/a$, where ξ is an integer number.

In any phenomenon involving an electron wave, the interaction with the “propagating waves” of the nuclei can change its momentum by $\pm \xi 2\pi\hbar/a$ and its k -value by an integer multiple of $2\pi/a$. To automatically take into account all these possible changes, when treating phenomena affecting the electrons we can first “fold” them into the so-called “first Brillouin zone” of k -values—centered at the origin and of width $2\pi/a$ as shown in Fig. 2c. We specifically see in the figure branches of the free-electron $E(k)$ curve “folded” into the first zone.

In addition to folding, the periodic potential of the nuclei has a second relevant effect. The electron waves reflected by the nuclei can interact between them. Particularly important is the case of waves with wavenumbers given by:

$$k = n\pi/a, \quad (5)$$

with $n = \text{integer}$ —the corresponding wavelengths being $2\pi/k = 2a/n$. Such wavelengths allow the waves reflected by different nuclei to interfere constructively between them. This is the equivalent for electron waves of the “Bragg reflections” for X-ray photons.

In practice, the waves obeying Eq. (5) are Bragg-reflected back and forth and cannot propagate. This means that their (group) velocity v_g is zero. From the equivalent of Eq. (4) we get:

$$v_g = (1/\hbar)(dE/dk), \quad (6)$$

thus v_g is zero if the $E(k)$ curve has zero derivative, e.g., it is at a maximum or a minimum. This implies that the periodic potential of the nuclei deforms the $E(k)$ curves as shown in Fig. 2d.

From this figure, we derive once again the existence of energy bands separated by forbidden gaps. This new derivation, however, is limited to periodic crystals—whereas the previous one, based on bonding and antibonding states, is more general.

Consider now the $E(k)$ curves folded in the first Brillouin zone—the so-called “band structure”—for energies close to the gap (Fig. 3a). We see at $T = 0$ K the completely filled valence band and the empty conduction band as in Fig. 1a. For each filled valence-band electronic state in the positive direction there is a symmetric state in the negative direction. We thus confirm what we already mentioned: the valence-band states are globally symmetric, so a completely filled valence band produces no overall electric current.

At $T > 0$ K, some electrons are thermally promoted to the conduction band becoming “free electrons.” Fig. 3b shows one free electron and the corresponding empty state in the valence band.

Fig. 3 (a) $E(k)$ plots for the valence and conduction bands of a one-dimensional semiconductor. At $T = 0$ K, the valence band is completely filled and the conduction band is empty. The valence-band electronic states are symmetric and there is no conduction. (b) Thermal excitation of an electron to the conduction band leaving an empty state in the valence band. (c) An external electric field F is applied in the positive direction: the conduction-band electron is subject to a negative force $-eF$ and shifts toward the negative side of the k -axis. This electron has negative charge $-e$ and negative group velocity $v_g = (1/\hbar)(dE/dk)$; therefore, its contribution $(-e)v_g$ to the current density is in the positive direction as the field F . The electrons in the valence band are also subject to the negative force $-eF$. But their “effective” mass $m^* = \hbar^2/(d^2E/dk^2)$ is negative, so the acceleration = force/mass is positive. Thus, they shift in the positive k -direction forcing the empty state to shift in the negative direction. The empty state now corresponds to an “unbalanced” electron whose contribution to the current is not offset by a symmetric electronic state. This unbalanced electron has negative charge and negative v_g , thus its contribution to the current is again in the positive direction. (d) The effects of the empty valence-band state can be described in terms of a pseudo-particle called “hole,” with positive charge $+e$ and positive group velocity: the dashed line shows its dispersion curve.

Suppose now that an external electric field F is applied in the positive direction (Fig. 3c). The conduction-band electron is subject to the force $-eF$ and moves to a negative value of k . The symmetry is broken allowing a current.

To describe the different contributions to this current, we must analyze in detail the effect of the applied electric field F . Its force can be treated with Newton’s equation:

$$\text{force} = -eF = dp/dt = \hbar dk/dt. \quad (7)$$

From the expression of the “group velocity,” Eq. (6), we get:

$$dv_g/dt = (1/\hbar)[d^2E/(dkdt)] = (1/\hbar)(d^2E/dk^2)(dk/dt),$$

which, combined with Eq. (7), becomes:

$$-eF = m^*(dv_g/dt), \quad (8)$$

that is, an equation of Newtonian form except that the free-electron mass m is replaced by an “effective mass”:

$$m^* = \hbar^2/(d^2E/dk^2). \quad (9)$$

In first approximation, the $E(k)$ curve near the minimum of the conduction band has a parabolic form whose second derivative is positive and does not change with k . So, m^* as defined by Eq. (9) is nearly constant as the real electron mass, although different in value.

Eq. (8) confirms our previous conclusion: the negative force $-eF$ on an electron at the bottom of the conduction band decreases v_g , causing the shift toward the negative side of the k -axis (Fig. 3c). The shift, however, does not continue indefinitely. Indeed, the effects of the external electric field are eventually countered by the scattering mechanisms responsible for resistivity.

The contribution to the current density of the conduction-band electron of Fig. 3c equals $-ev_g$, its negative charge multiplied by the group velocity of Eq. (6). Since v_g is negative, this contribution is in the positive direction—the direction of the electric field F .

But this is not the only contribution to the current caused by F . We must also consider the empty valence-band state in Fig. 3b. When the external electric field F is applied (Fig. 3c), all electrons in the valence band are subject to the negative force $-eF$. The effects are again described by Eq. (8). But now the effective masses of Eq. (9) are negative, so the acceleration is positive, shifting all valence-band electronic states in the positive k -direction. This pushes the empty state in the negative direction, as shown in Fig. 3c.

The valence-band electron opposite to the empty state is no longer balanced and produces a net current. This “unbalanced” electron has negative charge and negative group velocity. Thus, it produces a positive current—in the same direction as the electric field and as the current of the conduction-band electron. Summarizing, the total current is given by the combination of two contributions in the same direction, from electrons in the conduction band and from empty states in the valence band.

The effects of the empty valence-band states can also be treated in terms of the so-called “holes.” This notion is suggested by the fact that the “unbalanced electron” in Fig. 3c—with negative charge $-e$, negative m^* and negative v_g —gives the same contribution to the current as an imaginary pseudo-particle (“hole”) with positive charge $+e$, positive effective mass and positive group velocity $|v_g|$. The dispersion curve for this “hole” is shown by the dashed line in Fig. 3d.

The behavior of holes in semiconductor devices is easier to analyze than that of unbalanced electrons. The “holes” are, therefore, universally adopted when treating semiconductor electronics.

Our description was so far confined to one dimension. For a three-dimensional material, the wave number k is replaced by the k -vector $\mathbf{k}$. And the band structure does not consist only of $E(k)$ dispersion curves but of $E(\mathbf{k})$ surfaces. The top of the valence band and the bottom of the conduction band correspond to a maximum and to a minimum of such surfaces.

In three-dimensions, the effective mass is no longer a scalar quantity but a directional tensor. And several $E(\mathbf{k})$ surfaces can be found near the valence-band top and near the conduction-band bottom, corresponding to different effective masses for electrons and for holes.

Mobilities

The previous discussion justifies the following equation for the total current density created in a semiconductor by an external electric field F :

$$j = -nev_e + pev_h \quad (10)$$

where n and p are the free-electron density and the hole density. Here, v_e is the average group velocity for electrons in the conduction band. This average is determined by the balance between the effects of the applied field F and of the scattering mechanisms responsible for the resistivity (i.e., by impurities or defects or lattice vibrations). And v_h is the average group velocity for holes. Note (Fig. 3d) that the group velocities for electrons and holes are in opposite directions. Thus, the two terms on the right-hand side of Eq. (10) are both in the same direction, as expected.

In first approximation, v_e and v_h are proportional to the applied electric field F :

$$v_e = \mu_e F; \quad v_h = \mu_h F, \quad (11)$$

where the parameters μ_e and μ_h are called “electron mobility” and “hole mobility.” These are scalar quantities for a one-dimensional semiconductor. However, in a three-dimensional case they have directional character.

The combination of Eqs. (10) and (11) gives.

$$j = (-ne\mu_e + pe\mu_h)F, \quad (12)$$

where $(-ne\mu_e + pe\mu_h) = \sigma$ is the “conductivity.”

Eq. (12) implies a basic difference between the conduction in a semiconductor and that in a simple metal: the opposite effects of the temperature. In a metal, the temperature primarily affects the electron mobility. Indeed, as the temperature increases, the scatterings by lattice vibrations increase, and the mobility decreases as well as the conductivity. In a semiconductor, the temperature affects not only the mobilities but also the carrier densities n and p —which increase as the temperature increases. This last effect dominates, so the conductivity of a semiconductor increases with the temperature—whereas in a metal it decreases.

Doping

What, besides the Fermi-Dirac function, can influence the free-electron concentration n and the hole concentration p in a semiconductor? We can easily understand that they can be modified by impurities: let us see how.

So far, we have assumed that the forbidden gap contains no electronic states. Therefore, each hole corresponds to an empty state in the valence-band and to a free electron in the conduction band. Thus, $n = p$.

We can realize from Fig. 1b that n and p are determined by the Fermi-Dirac function, and specifically by the position of E_F with respect to the valence and conduction bands. And we can intuitively understand that the $n = p$ condition requires E_F to be close to the middle of the gap (Fig. 4a).

Another important implication of the $n = p$ condition can be discovered with the so-called “law of mass action.” The mathematical form of the Fermi-Dirac function is $1/\{\exp.[(E-E_F)/(kT)] + 1\}$, where k is the Boltzmann constant. Assume

Fig. 4 (a) In an ideal semiconductor completely free from impurities, the condition $n = p$ implies that the Fermi level E_F is close to the middle of the gap. (b) An arsenic impurity in a silicon crystal: four of its electrons are engaged in sp^3 chemical bonds with neighboring silicon atoms. The fifth one is in a “nonbonding” (impurity) state. (c) The corresponding impurity energy level is inside the gap and near the bottom of the conduction band. At finite temperatures, the impurity levels can “donate” electrons to the conduction band by thermal excitation. (d) Symmetrically, an impurity with three valence electrons per atom such as gallium can inject holes in the valence band acting as an “acceptor”.

(Fig. 1b) that all the free electrons are close to the bottom of the conduction band E_c , and all the holes are close to the top of the valence band E_v . Further assume that E_F is far from both E_c and E_v , i.e., near the middle of the gap.

Then, the free-electron density n is proportional to the Fermi-Dirac function at E_c , $1/\{\exp[(E_c - E_F)/(kT)] + 1\} \approx \exp[(E_F - E_c)/(kT)]$. Symmetrically, p is proportional to $\approx \exp[(E_v - E_F)/(kT)]$. And the product np is approximately proportional to $\exp[(E_v - E_c)/(kT)] = \exp[-E_g/(kT)]$. Thus, np is only a function of the temperature, independent of the position of E_F . For a fixed temperature, it is a constant: this is the aforementioned “law of mass action.”

It can be easily shown that if np is constant the condition $n = p$ gives the minimum value of the total carrier density $n + p$. One cannot increase the carrier density above this minimum if each free electron corresponds to a hole.

To break this condition, however, one can “dope” the semiconductor by adding impurities in a controlled way. How do the impurities work?

Consider, for example (Fig. 4b), arsenic impurities in a silicon crystal. The chemical bonds in pure silicon are formed by the sp^3 hybridization of four $3s$ and $3p$ valence electrons for each atom. An atom forms chemical bonds with four nearest neighbors; thus, each bond involves two electrons, one per atom. The “bonding” sp^3 hybridized states correspond to the valence band, whereas the “antibonding” ones correspond to the conduction band.

Suppose now that one silicon atom is replaced by an arsenic atom with five rather than four valence electrons (Fig. 4b). Four of them form chemical bonds with neighboring silicon atoms, and the corresponding sp^3 states contribute to the conduction and valence bands. The fifth arsenic electron is not engaged in chemical bonding: its state is “nonbonding.” And its energy is intermediate between those of the “bonding” and “antibonding” states. Thus, it falls within the forbidden gap (Fig. 4c).

Not being engaged in a chemical bond, this electron can be easily freed from the impurity and promoted to the conduction band. This means that the impurity energy level is close to the bottom of the conduction band, as seen in Fig. 4c. Thermal excitation easily allows the impurity to “donate” electrons to the conduction band: this is why arsenic in silicon is called a “donor” impurity.

At $T = 0\text{ K}$, however, there is no thermal excitation at all: the donor electronic states are all full and the conduction band states are empty. Thus (Fig. 4c), the Fermi level falls between the donor energy level and the bottom of the conduction band—and is no longer close to the middle of the gap.

At $T > 0\text{ K}$, electrons are thermally promoted from the impurity level to the conduction band. The corresponding energy distance is smaller than E_g , so there is a large concentration n of impurity-donated free electrons. The $n = p$ rule is broken and the total carrier density $n + p$ is larger than the minimum value. The material is an “ n -type” semiconductor, whereas an impurity-free sample with $n = p$ is an “intrinsic” semiconductor.

A symmetric mechanism enables impurities with three valence electrons per atom (“acceptors”)—such as gallium—to inject a large number of holes in the silicon valence band—producing a “ p -type” material. In this case (Fig. 4d), the impurity has an empty

level near the top of the valence band that can easily capture thermally excited electrons from the valence band. This creates empty states in the valence band and increases the hole density p .

At $T = 0$ K, however, all acceptor levels are empty and all valence band states are filled. Thus, the Fermi for a p -type material level falls between the top of the valence band and the acceptor impurity level—see Fig. 4d.

Impurities are normally present in a semiconductor, so that the samples are naturally doped n -type or p -type. But chemical processes can change the character from p to n and vice versa.

Quite difficult, however, is to produce samples with low impurity concentrations, so that $n = p$, the total carrier concentration $n + p$ is low, and the material has low conduction. The $n = p$ condition is more easily achieved with high but equal concentrations of donors and acceptors. An intrinsic material of this kind is said to be “compensated.”

Current rectification by Schottky diodes and p - n junctions

Controlling the transport properties by doping is a key factor in the realization of semiconductor devices. Two simple examples are qualitatively discussed here: the Schottky barrier and the p - n junction, both of which are building blocks of many complex devices.

A Schottky barrier (Fig. 5a) is formed by joining a semiconductor and a metal. The semiconductor can be either n -type or p -type. We shall consider here (Fig. 5b and c) the n -type case—the analysis for the p -type case being symmetrical and based on holes.

Fig. 5 (a) Structure of a metal-semiconductor Schottky diode. (b) Band structure before the two sides are joined together. (c) Band structure after the junction is formed, producing the band bending in the “depletion layer” and creating a barrier ΔE . (d) The barrier is increased by a “reverse” bias, whereas (e) it is decreased by a “forward” bias. (f) Current-voltage curve showing the rectification.

Imagine (Fig. 5b) the semiconductor still separated from the metal: the Fermi level is not the same for the two materials. Consider now the “vacuum level” E_L , i.e., the minimum energy for an electron to be completely free from a material. E_L is the same for the metal and for the semiconductor. We shall define the “work function” of the metal, Φ , as the difference between E_L and the metal Fermi level. And we shall define χ , the “electron affinity” of the semiconductor, as the difference between E_L and the bottom of the conduction band, E_c .

When the metal and the semiconductor are brought in direct contact, their Fermi levels cannot remain different. Otherwise, it would be possible to lower the energy of the system by moving electrons to lower-energy states, whereas equilibrium corresponds to a minimum of the total energy. To equalize E_F , electrons in the semiconductor donor levels near the interface quit them, leaving the donors positively charged. The result is an electric field at the interface preventing more electrons from leaving the semiconductor.

The new equilibrium situation is shown in Fig. 5c, with the same Fermi level everywhere and a “band bending” on the semiconductor side caused by the electric field of the positively charged donors. In the “band bending” region, E_F is below the donor levels and close to midgap. Thus, the region is an insulating “depletion layer” with no carriers.

Because of the electric field of the charged donors and of the consequent band bending, electrons at the bottom of the conduction band in the semiconductor face an energy barrier ΔE . This barrier prevents them from diffusing across the depletion layer and reaching the metal.

Assume now that an external voltage bias is applied to the junction trying to create a current (Fig. 5d). The voltage drop occurs across the insulating “depletion” layer, changing the band bending and ΔE .

If the bias is in the “reverse” direction of Fig. 5d, it acts against the passage of electrons from the semiconductor to the metal. This means that the barrier ΔE is further increased. However, the barrier was already high enough to prevent a current of free electrons. Thus, the reverse bias causes no changes and in particular no current.

On the contrary (Fig. 5e), if the voltage bias attracts electrons to the metal, then the barrier ΔE is decreased facilitating the flow of electrons. This “forward” bias thus creates a current, as shown in Fig. 5f.

Overall, therefore, the metal-semiconductor junction acts as a rectifying diode, allowing a current to be created only in one direction. However, we see in Fig. 5f that a “reverse” voltage bias eventually reaches a level that causes a large current. This is due to a so-called “avalanche” mechanism and limits the operating voltage-bias range of the rectifying diode.

The behavior of Fig. 5f finds wide applications in electronics. And it is primarily characterized by the barrier parameter ΔV . We can see from Fig. 5c that:

$$\Delta E = \Phi - \chi, \quad (13)$$

therefore, for a given semiconductor different metals should give different Schottky barriers according to their work functions.

This, however, is often not true. The reason is the creation of electronic states localized at the interface when the junction is formed. Such states can locally “pin” the Fermi level and influence the barrier. In general, both the interface states and the metal work function determine ΔE . The interplay of such mechanisms is quite complicated and changes from interface to interface.

We shall now analyze another widely used rectifying device, the p - n junction. Which consists of a semiconductor sample with two different regions, one n -type and the other p -type (Fig. 6a). In practice, the junction can be fabricated starting from a sample of one type and then changing the doping of part of it with a suitable procedure, such as gas-phase exposure.

In the band diagram of the np junction (Fig. 6b) the n -type and p -type regions are again separated by a “depletion layer”—where E_F is close to the middle of the gap. This situation is similar to an insulating (intrinsic or compensated) semiconductor with low total carrier density. As for Schottky junctions, the Fermi level must be the same everywhere. Thus, in the depletion region there is a band bending and an energy barrier ΔE .

Free electrons do not cross from the n -region to the p -region due to the energy barrier. Similarly, holes in the p -region do not cross to the n -region since they face a symmetric barrier.

Imagine now that an external voltage bias V is applied to the junction, trying to create a current. A “reverse” bias (Fig. 6c), positive on the n -side and negative on the p -side, increases the ΔE barrier, making it even more difficult for carriers to cross the junction—so that no (or very little) current is produced. On the contrary, a “forward” bias (Fig. 6d) decreases the barrier and makes it easier for electrons and holes to cross it, producing a current.

Overall, the junction exhibits a rectifying behavior similar to that shown in Fig. 5f for Schottky diodes. Under rather idealized hypotheses, the current I can be described (except for the reverse-bias breakdown) by the equation:

$$I = I_0 \{ \exp.[eV/(\eta kT)] - 1 \} \quad (14)$$

where V the applied voltage bias, k the Boltzmann constant, and η the so-called “ideality factor” ($\eta = 1$ being the limit, most ideal case).

The above descriptions of Schottky diodes and p - n junctions are oversimplified. However, they are suitable to understand the basic facts and, in particular, the crucial role of doping in the fabrication of semiconductor devices.

Fig. 6 (a) A p - n junction and (b) the corresponding energy band diagram. Free electrons from the n -side cannot cross the depletion region due to the energy barrier ΔE . A symmetric conclusion is valid for holes from the p -side. (c) An external voltage bias applied in the “reverse” direction increases the barrier ΔE and generates no current. (d) A “forward” bias decreases the barrier making it easier for electrons and holes to overcome it, producing a current.

Heterojunctions and field-effect transistors

Certain electronic devices include the so-called “heterojunctions.” These are combinations of two different semiconducting materials with different gaps. One example is shown in Fig. 7, which illustrates the band diagram of the junction of a large-gap p -type materials and a small-gap n -type material.

The diagram exhibits a feature not found in p - n junctions nor in Schottky diodes: band discontinuities. Such discontinuities are required to accommodate the difference between the two gaps, which is partitioned between the valence and conduction band discontinuities ΔE_v and ΔE_c .

The possibility to control this partitioning adds flexibility to the design of devices. This control can be achieved with suitable fabrication procedures, in the framework of the so-called “bandgap engineering.”

Semiconductors are now used in a huge variety of devices, many of them composed by a few basic “building blocks.” Besides the rectifying diodes, one must note the transistors, operating as switches or as amplifiers.

Quite common are the “bipolar junction” transistors. However, the most widely used today are, by far, the field-effect transistors (FETs). And the majority of these are the “MOSFETs” (metal-oxide-semiconductor FETs).

Fig. 7 (a) Band diagrams of two different semiconductors with different gap widths before forming a heterojunction. (b) The formed heterojunction with the valence and conduction band discontinuities ΔE_v and ΔE_c that accommodate the gap difference.

Fig. 8 Simplified cross-sectional schemes of the MOSFET structure, with the two possible doping configurations.

The present impact of the MOSFET technology on microelectronics defies the imagination. The total number included in one integrated device recently (2021) approached 60 billion. And the estimated number of MOSFETs produced every year in the world exceeds 10^{22} (ten thousand billions of billions). Which is half million times larger than the number of rice grains harvested worldwide (and the unit cost of MOSFETs is much lower).

Fig. 8 shows a simplified scheme of a MOSFET structure. In essence, the device controls the current flowing between the two electrodes “source” and “drain,” connected to two *n*-type semiconductor regions separated by a *p*-type region (or to two *p*-type regions separated by a *n*-type region). The control is achieved by applying a voltage to a third electrode, the “gate,” connected to a conducting (metal or polycrystalline silicon) region, which sits on a very thin insulating layer (typically silicon oxide).

The control mechanism (“field effect”) is very efficient. And the MOSFET structure is suitable for extreme miniaturization, packing huge numbers in each integrated device. This explains its leading present role in microelectronics.

Important semiconducting materials

Many different elemental and compound semiconductors have a potential for applications but only a few are actually used. Among these, silicon largely dominates—in particular in the MOSFETs. This is due to its very advanced technologies and to some specific properties. For example, the quality of its oxide as an insulating (passivating) layer and the success in growing very large high-quality crystals.

In addition to Si, also used for practical applications are germanium and some III–V compounds, such as GaAs, GaP, InP, and GaN. And increasingly important are the organic semiconductors.

Silicon and germanium

Both of these elemental materials have, in their crystalline forms, the cubic structure of diamond shown in Fig. 9a. In which each atom is tetrahedrally bound to its four nearest neighbors.

The band structures of the two materials are shown in Figs. 9b and c. Here, $E(k)$ curves are plotted along two high-symmetry crystallographic directions, $\langle 111 \rangle$ and $\langle 100 \rangle$.

For both materials, the bottom of the conduction band and the top of the valence band occur for two different k -vectors. The corresponding gaps are called “indirect,” whereas when the bottom of the conduction band and the top of the valence band occur for the same k -vector the gap is “direct”—as seen for the GaAs band structure in Fig. 10b.

The direct or indirect character of the gap strongly influences the physical properties of the material. For example, the transitions of electrons across the gap imply no change of the k -vector for a direct gap, whereas the contrary is true for an indirect gap. And a

Fig. 9 (a): the characteristic tetrahedrally coordinated cubic diamond crystal structure of silicon and germanium. (b) Band structure of silicon along the $\langle 111 \rangle$ and $\langle 100 \rangle$ directions of the k -vector. Note that the gap is “indirect”: the conduction-band minimum is at a different k -vector than the valence-band maximum. (c) The band structure of germanium also has an indirect gap.

Fig. 10 (a): the zincblende crystal structure of many III–V semiconductors. (b) Band structure of GaAs with its direct gap.

change in the k -vector corresponds to a change in the momentum. This requires the intervention of another party—such as a lattice vibration—to guarantee momentum conservation.

Note that for both the Si and Ge band structures there are two $E(k)$ curves at the top of the valence band, with different curvatures d^2E/dk^2 —corresponding to differences in the effective masses (Eq. (9)). Holes can belong to either one of them, so they can have different m^* values. Accordingly, the two valence-band $E(k)$ curves in Figs. 9b and c are called “heavy-hole” band and “light-hole” band.

These are the values of some important parameters of Si and Ge (the effective masses are expressed in terms of the free electron mass):

	Si	Ge
E_g (300 K)	1.12 eV	0.67 eV
Electron effective masses (heavy and light)	0.98, 0.19	1.6, 0.08
Hole effective masses (heavy and light)	0.49, 0.16	0.33, 0.04

III–V compounds and organic semiconductors

Binary materials in the III–V class exhibit a wide spectrum of properties of concrete or potential interest for practical applications. Fig. 10a shows the typical zincblende crystal structure of many of such compounds. This structure is related to that of diamond, but it includes two atomic species rather than one.

Fig. 10b shows the band structure of the leading III–V semiconductors, GaAs. As for Si and Ge, we see heavy-hole and light-hole bands. The gap is direct for GaAs but not for all III–V compounds: for example, it is indirect for GaP. The gap widths at 300 K for the important III–V semiconductors GaAs, GaP, InP, and GaN are 1.42, 2.26, 1.35, and 3.44 eV.

There exist many more semiconducting materials than those mentioned above. We shall limit our attention on a few additional ones because of their massive applications.

Optical properties and their applications

Quite important are the semiconductors used in devices emitting visible light—for illumination and for the displays of computers, portable telephones or television sets. As we shall see shortly, the production of visible light requires materials with large gaps. A typical example is GaN, whereas Si is not ideal because of its rather small gap.

GaN is indeed largely used at present for “light-emitting diodes” (LEDs). There is, however, a strong competition with “organic” LEDs (OLEDs), based on organic semiconductors formed by small organic molecules or by polymers.

Strictly speaking, organic semiconductors are not really semiconductors but insulators because of their large gaps. However, they share with conventional semiconductors important properties such as the possibility to inject electron and holes with biased electrodes.

Both LEDs and OLEDs offer advantages and disadvantages. For example, the efficiency and image quality of OLED displays is superior, but the lifetime is typically shorter. Technological research for both classes of materials is very active, so the relative weight of advantages and disadvantages could significantly change in the future.

The operation of LEDs is based on the interactions of semiconductors with photons. In turn, such interactions are dominated by the forbidden gaps. For example, electronic transitions between the valence band and the conduction band cannot cause the emission or absorption of photons of energy smaller than E_g (without involving impurity levels).

Note that the gaps of Si and Ge correspond to infrared photon energies, so they are not ideal for visible-light devices. This is also true for GaAs and InP, whereas for GaP E_g corresponds to visible photons and for GaN to the border between ultraviolet and visible.

Fig. 11 Absorption coefficient of silicon measured for two temperatures in the photon energy range near the gap width value E_g . Note the steep threshold related to E_g .

Fig. 11 shows the absorption coefficient of silicon plotted in a photon energy range near E_g . There is a sharp edge: the absorption is minimal below E_g , but it rapidly increases above it due to optical transitions of valence-band electrons to empty states above the gap.

Photon emission is symmetric to photon absorption. The process takes place when electrons are injected in the conduction band and undergo optical transitions to empty states in the valence band. Such transitions can be also described as the recombination of electrons and holes.

Real optical processes are often more complicated than the above simplified descriptions. Which, for example, did not consider the interactions between electrons. In reality, the electrons do interact—in particular, the free electrons in the conduction band with the electrons in the valence band. This causes the so-called “excitonic effects.”

The simplest case of such effects is the formation of “Wannier excitons.” An exciton of this kind is created by the Coulomb attraction between a free electron and a hole, binding them together. The two particles form a system similar to a hydrogen atom, in which the proton is replaced by a much lighter hole and the dielectric constant is that of the semiconducting material.

A Wannier exciton has bound states corresponding to hydrogen-like energy levels, whereas its ionization states constitute the conduction band. This kind of exciton is quite delocalized, justifying the use of effective masses—whereas the so-called “Frenkel” excitons are localized.

The excitation of an electron from the valence band by absorption of a photon can take place in two different ways: by entirely freeing the electron into the conduction band or by forming an exciton. The latter corresponds to a transition to one of the exciton energy levels.

Therefore, in the plot of absorption vs. the photon energy the “continuum” above the E_g edge is preceded by excitonic absorption peaks. The first peak corresponds to the creation of an exciton in the ground 1s hydrogen-like level. And other discrete levels can produce other peaks.

However, the actual detection of excitonic peaks is not easy, since it requires sufficient spectral resolution and a low temperature to avoid excessive thermal broadening. Fig. 12a shows that excitonic absorption peaks are indeed seen for GaAs when the temperature is low.

Fig. 12 On the left: excitonic peaks in the low-temperature absorption spectrum of GaAs. On the right: the absorption edge of indirect-gap GaP, also at low temperature. The arrows mark spectral features related to the gap and to specific phonons that guarantee the momentum conservation.

Photon absorption becomes more complicated when the gap is not direct as for GaAs, but indirect. As mentioned above, the optical transitions must be assisted by a suitable “third party” besides the photon and the electron (or the hole)—which guarantee the conservation of the momentum. Lattice vibrations (i.e., phonons) can play this role.

Fig. 12b illustrate this point with the absorption edge of indirect-gap GaP. We see several spectral features related to the participation of specific phonons that absorb part of the photon energy and contribute to the momentum. As for excitonic peaks, the detection of these features requires low temperature and high spectral resolution.

Excitonic effects affect not only the absorption but also the emission of photons. In that case, the important excitons are those “bound” to impurities.

In general terms, impurity levels in the forbidden gap allow the emission (and the absorption) of photons with energies smaller than E_g . Consider, for example, GaP: its room-temperature gap, 2.26 eV, corresponds to green visible photons. The corresponding light-emitting devices could be quite effective since the peak of the human eye response occurs for green light.

However, photon emission from pure GaP is rather ineffective, because its indirect gap requires the intervention of phonons as seen in Fig. 12b, limiting the electron–hole recombination rates. Doped GaP can be more effective in some cases by not requiring phonons, but its emission corresponds to excitonic impurity levels in the gap. The emitted photons are no longer green but shifted to the red—where the human eye is less efficient.

From the above discussion, we can realize that the ideal semiconducting material for visible LEDs should have a large gap and be suitable for doping with different types of impurities. Such impurities can produce optical transitions at different photon energies smaller than the gap, ideally covering the entire visible spectrum. The material can then emit different colors and be used in LEDs for variable color emission or for white light.

We have seen that an excellent solution is offered by the wide gap of GaN. Doped with suitable impurities, GaN emits blue light as well as other colors. In recent decades, excellent progress in the GaN technology led to the aforementioned fabrication of very efficient white-emitting LEDs. The rather spectacular results are now visible in everyday life.

LED mechanism

How does a semiconductor LED work? Fig. 13a schematically shows a simple type based on a forward-biased p – n junction. As we have seen, this bias lowers the barriers for electrons and holes. Electrons from the n -region can cross the junction into the p -region, where they find a large density of holes. This allows electron–hole recombination and the emission of photons.

Symmetrically, the reduced barrier enables some holes to cross from the p -region to the n -region. There, they find a large density of free electrons, and produce photons by electron–hole recombination.

The p – n junction is also the foundation of another important type of optoelectronic device: light detectors or photodiodes. Fig. 13b schematically shows how it operates.

The p – n junction is now reverse biased, so that normally very little current flows through it. When photons with energies larger than E_g reach the junction, they excite electrons into the conduction band. Suppose that the excitation occurs in the interface region. The free electrons find a voltage drop that sweeps them into the n -region and then to the external circuit. Symmetrically, the holes are swept into the p -region, also contributing to the current. The photon beam thus produces a photocurrent that reveals its arrival on the diode—which acts as a light detector.

Fig. 13 Simple types of semiconductor optoelectronic devices based on the p – n junction. (a) The forward bias of an LED lowers the barriers for electrons and holes, which can cross the junction reaching the opposite region, where they recombine and emit photons. (b) With reverse bias, very little current normally flows through the junction. When photons with energy larger than the gap illuminate the device, they can excite electrons within the depletion layer into the conduction band, creating holes. The bias sweeps these electrons into the n -region and the holes into the p -region, from which they can reach the external circuit and cause a photocurrent. The junction can thus operate as a light detector or a solar cell.

Similar to the light detectors are the semiconductor solar cells—that convert the energy of photons into electric power, providing an alternate source of energy of increasing importance. In this case, the semiconductor materials must be optimized for the absorption of a large part of the solar spectrum.

The solar cell technology is currently dominated by silicon. However, alternate solutions have emerged like the “Graetzel” cells and the solar cells based on materials of the class “perovskites.” Time will identify the winning technology—or perhaps the winning combination of different approaches.

Conclusion

The transport and optical properties linked to the electron energy structure of semiconductors led to practical devices that influence every aspect of our life today. There is no question that this role will continue in the future. In fact, the expanded use of properties like the optical absorption will further expand this role, in particular in strategic areas like the production of clean energy.

Abstract

Excitons are the lowest energy optical excitation in a semiconductor. Light absorbed by a semiconductor above the bandgap creates an electron-hole pair which is then bound by the Coulomb attraction to form an atomic-like bound state, that may nonetheless be mobile throughout the solid, and is a composite boson. Excitons may have excited states, may form complexes with multiple excitons, and may bind extra electrons or holes to form charged ‘trions.’ When there is a dipole-allowed recombination to a photon, there is a composite boson formed known as a polariton. Polaritons are bosonic quasiparticles with a very light mass, and can form a phase-coherent ground state that is a non-equilibrium Bose Einstein condensate.

Introduction and basic ideas

The electronic band structure in a solid gives a formal accounting of the excitation energy $E_n(\mathbf{k})$ for adding to the ground state of the system a *single* carrier in the state of momentum $\mathbf{k}$. If the energy is greater than the chemical potential - i.e. an empty state - this refers to an electron; if the energy is below the chemical potential - a filled state - the excitation is a hole. In a semiconductor or insulator there is a gap between the creation of electrons and holes. Of course adding one electron and one hole in different bands or with different momenta creates an excited state of the system - and if the electrons and holes did not interact, we could of course enumerate the energies of the excited states just from the one-particle bands. However, the electron and hole are oppositely charged and therefore attract - the minimum energy required to create an electron-hole pair is therefore always less than to create either particle separately. The attraction between these two oppositely charged single particle excitations creates a bound state called an *exciton* - just as the Coulomb attraction between a proton and an electron creates the bound states of the Hydrogen atom. This is schematically described in Fig. 1.

Excitons recapitulate within a solid much of the physics of solids themselves, but with the added richness provided by the complexity of the bandstructure on which they are based. There are varieties of excitons, just as there are varieties of excited atomic states. Excitons themselves interact: there exist excitonic molecules, excitonic liquids, and possibly even coherent condensed states akin to the Bose-Einstein condensation of cold atoms - though these have not yet been unequivocally observed. In some materials, excitons are heavy and easily localized, whereas in others they are very light and readily propagate throughout the solid. Excitons are composite

Fig. 1 On the left is a sketch of the lowest conduction $E_c(k)$ and highest valence $E_v(k)$ bands for a simple direct gap semiconductor with a quadratic dispersion and masses for electron and hole of m_e, m_h . If these bands described non-interacting particles, the lowest excitation energy of total wavevector q is then $E_0 + \hbar^2 q^2/2M$, where $M = m_e + m_h$, which marks the edge of a continuum of excitations of free electrons and free holes, shown by the gray hatched region on the right. Allowing for the binding of the electron and hole, the lowest excitations are now excitons - a series of discrete states that disperse approximately parallel to the bottom of the continuum, but shifted downward by the binding energy E_B .

bosons (formed from two fermions) and have spin degrees of freedom. They may trap on defects and disorder, and may also have strong interactions with the lattice leading to the formation of excitonic polarons. And most importantly, excitons often interact strongly with light, so that they are often the dominant feature in optical spectra of solids. Excitons may be observed in such a case by their absorption profile, but more frequently by their luminescence - the recombination emission of light which is therefore at the total energy of the electron-hole pair. Even if they do not decay radiatively, excitons are of course transient phenomena - they have a finite lifetime, which can however be very long in some materials at low temperature. Good overviews of this broad topic are available in several books (Knox, 1963; Cho, 1979). Excitons and excitonic physics are important for practical applications of photonics in semiconductors, including lasers, light-emitting diodes, and solar cells (Chuang, 1995; Haug and Koch, 1993).

Binding of excitons

Frenkel excitons

Conceptually the simplest picture of an exciton emerges for crystals made of tightly bound electron states, such as rare gases or highly ionic solids. In these materials the electronic bands are narrow, and excitations within the solid are thus nearly localized. An atomic excited state, embedded within a lattice of unexcited atoms, is a cartoon for a *Frenkel exciton* - but of course since all the atoms in the solid are identical this excitation hops from atom to atom throughout the solid to form a weakly dispersing band with a large mass. While the original concept of a Frenkel exciton was based on a transition occurring in a lattice of neutral atoms, highly localized excitons may also involve charge transfer between orbitals on nearby atoms or groups of atoms. This latter is often the dominant situation in polymers, and organic materials (Davydov, 1971). Often the correct description is a mixture of Frenkel and charge transfer exciton, as one can see in Fig. 2 by the shift of absorption and the development of new structure between an isolated molecule, and a crystal.

Generally, these highly localized excitons require detailed microscopic theory to analyse their spectral structure. Being localized, they couple strongly to vibrational degrees of freedom of the molecule, often producing extra “vibronic” structure.

Hydrogenic excitons

The opposing limit of weakly bound excitons is much more straightforward to analyse, and this produces the excitons familiar in direct gap semiconductors such as GaAs. Here the band dispersion is large, so that the energy cost of occupying states of large momentum $k \approx \pi/a$ (where a is the lattice constant) is large. Hence the excitonic bound state is a wavepacket made up from electron and hole states near $k \approx 0$. The valence and conduction band states are Bloch states, of the form

$$\psi_{nk}(\mathbf{r}) = u_{nk}(\mathbf{r})e^{ik \cdot \mathbf{r}}, \quad (1)$$

where u is a periodic function on the crystal lattice, and $n = c, v$ will refer to the conduction and valence bands respectively. If we neglect the momentum dependence of u_{nk} , the wavefunction for an exciton becomes separable,

$$\Psi(\mathbf{r}_e, \mathbf{r}_h) = u_{ck=0}(\mathbf{r}_e) \times u_{vk=0}(\mathbf{r}_h) \times f(\mathbf{r}_e - \mathbf{r}_h) \times e^{iq \cdot \mathbf{R}}. \quad (2)$$

Here $\mathbf{R}$ is the center of mass coordinate, and q the corresponding momentum (see Fig. 1). $f(\mathbf{r})$ is the exciton wavefunction in relative coordinates, and satisfies the Schrödinger equation

$$\left[-\frac{\hbar^2}{2\mu} \nabla^2 - \frac{e^2}{4\pi\epsilon\epsilon_0 r} \right] f(\mathbf{r}) = (E - E_0)f(\mathbf{r}). \quad (3)$$

where $\mu = m_e m_h / (m_e + m_h)$ is the reduced mass, ϵ the relative dielectric constant, and E_0 the single particle gap.

Fig. 2 A comparison of absorption spectra of monomers with crystals where the excitons are highly localized. (A) shows the absorption of isolated molecules in solution, whereas (B) shows the optical density of a polycrystalline film of the same material. The thick curve is at 5 K in p-polarization and the thin curve at 293 K in s-polarization. (C) is from a crystalline film of a similar compound at 5 K. Reproduced with permission from Hoffmann M, Schmidt K, Fritz T, Hasche T, Agranovich VM, and Leo K (2000) *Chemical Physics* 258: 73.

This Wannier exciton then has the spectrum of a hydrogen atom, with the difference being that in direct gap semiconductors like GaAs the effective mass is small ($\mu/m \approx 0.1$) and the dielectric constant is large ($\epsilon \approx 10$). This means that the binding energy

$$E_B = \frac{\mu e^4}{8\epsilon^2 \epsilon_0^2 h^2} = \frac{\mu}{m} \frac{1}{\epsilon^2} \text{Ryd}. \quad (4)$$

may be a small fraction of the Rydberg ($\text{Ryd} = 13.6 \text{ eV}$). The size of the exciton is given by an effective Bohr radius

$$a^* = \frac{\epsilon \epsilon_0 h^2}{\pi \mu e^2} = \epsilon \frac{m}{\mu} a_0 \quad (5)$$

much larger than the Hydrogen Bohr radius $a_0 = 0.05 \text{ nm}$. Thus the wavefunction extends over several unit cells, which justifies the approximate expression made for the wavefunction in eq. (2). The hydrogenic-like series of lines is well seen in the higher principal quantum number states in Cu_2O , Fig. 3.

Fig. 3 Exciton spectrum in Cu_2O . The upper panel is derived from one-photon absorption (and thus begins with the 2p state) and the lower panel shows the two photon absorption, showing thus s- and d- series. The insets show the full spectrum. Reproduced with permission from Matsumoto H et al. (1996) *Solid State Communications* 97: 125.

Indirect excitons

It is not necessary for exciton states correspond to vertical band transitions (i.e. $q = 0$ in Fig. 1) because we can construct a wave packet about *any* band extremum. So for example in Ge the lowest excited state is made from wave packets of holes at $k = 0$ and electrons at the equivalent conduction band minima along the [111] direction at the Brillouin zone boundary. A similar situation pertains for Si, except that the electrons are confined to six pockets in the [100] directions (inside the Brillouin zone). These excitons are called *indirect* because they require a non-zero momentum to connect the electron and hole. Momentum conservation then does not allow the exciton to directly decay into a photon, and one requires either a process involving recombination also with emission of a phonon, or scattering from an impurity or a surface or other confinement. This is typically very inefficient, which is why Si is not used for optical devices.

Confined excitons: Quantum wells, wires, and dots

The engineering of quantum wells in semiconductors can also be used to manipulate excitonic states. In $\text{GaAs}/\text{Ga}_{1-x}\text{Al}_x\text{As}$ quantum wells (the canonical system, though many of the III-V and II-VI series are used) one may confine both electron and hole to a narrow sheet, comparable or smaller in size than the effective Bohr radius a^* . It is also possible to create more complicated structures including quantum wires, and quantum dots. There are two principal effects. Firstly, the extra confinement brings the electron and hole closer together and increases (sometimes substantially) the binding energy producing a shift in the energy of absorption and luminescence in comparison to bulk material. The second effect arises because of the structure of the top of the valence band which in a bulk system has a degeneracy between the light and heavy hole bands at $k = 0$ (the states are p-like, which therefore have a threefold orbital degeneracy under cubic symmetry; with spin-orbit coupling the pair of bands are the fourfold-degenerate $J = 3/2$).

Fig. 4 Luminescence of a 7.5 nm CdSe nanocrystal shows the quantum confined Stark effect. The position of the exciton line shifts under a range of electric fields - values in kV/cm are shown for each trace. Reproduced with permission from Empedocles SA and Bawendi MG (1997) *Science* 278: 2114.

This degeneracy is broken by the quantum well, which fixes a local axis, and splits the light and heavy hole bands, leading to a further separation of the two types of exciton.

The exciton energy, and its binding, are affected by applied electric fields, since an applied field will pull the electron and hole apart from each other. In a bulk system quite small fields can ionize the exciton, but if the exciton is confined either to a well or a quantum dot (see Fig. 4) the electron and hole will be trapped and very large shifts of the exciton luminescence with electric fields can be produced. This is the *quantum-confined Stark effect*, a principle used in semiconductor laser modulators.

Interactions between excitons

Excitonic molecules and complexes

Like atoms, excitons interact and may bind to form molecules and other complexes. Atomic H binds to form H_2 in an exothermic reaction that generates about $1/3$ Ryd. per molecule. The analog of H_2 is the biexciton (sometimes labeled as X_2) - which is however typically less bound than H_2 because of the finite hole mass. In a bulk semiconductor with equal mass electrons and holes, the binding energy of a (hydrogenic) biexciton is about $0.03 E_B$, proportionately one order of magnitude smaller than for H_2 ; but in GaAs, where the hole is proportionately heavy, the binding energy can be substantial (see Fig. 5).

Stable species can also be made when excitons bind to electrons and holes (*trions*) - a situation which can arise upon optical excitation of a low-density electron or hole gas in a semiconductor. In general, many exciton complexes have been discovered.

Electron-hole liquid

If the density of excitons is increased so that they overlap, they lose their individual character as atoms, as the electrons and holes become unbound. The high density two-component plasma so formed is then an electrical conductor - with one fermi surface each for electrons and holes - similar to an equilibrium semimetal. The transition between the excitonic insulator and the plasma state occurs at the density $n(a^*)^d \approx 1$ as for the Mott metal-insulator transition. This has for many years been a focus of study in semiconductors because the large effective Bohr radius means that this regime can be reached at moderate excitation levels. A typical semiconductor laser is in this density range, though also usually at a temperature well exceeding the exciton binding energy.

Fig. 5 Optical emission from excitons and biexcitons in GaAs, normalized to the intensity of the excitonic peak and resulting from optical pumping at an energy well above the exciton emission. At increasing intensities of illumination, the biexciton emission grows because two excitons must collide and bind within the time scale for recombination. The solid line is a fit to the data. Fig. 6 Electron-hole liquid in Ge. A photograph of a droplet of electron-hole liquid at 2 K in a 4 mm diameter Ge disk, stressed by a nylon screw (top) along (110) and viewed through an (001) face. The central bright region is the e-h recombination luminescence from the liquid confined in a potential well of maximum shear stress. The bright ring around the sample is recombination luminescence scattered from the surface of the crystal. Reproduced with permission from Markiewicz RS, Wolfe JP, and Jeffries CD (1977) *Physical Review B* 15: 1988.

In Si and Ge, it turns out that the dense plasma phase is lower in energy than to distribute the electron-hole pairs as a dilute gas of excitons or biexcitons. The origin of this phenomenon is the multivalley nature of the conduction band in these materials - in the plasma phase the kinetic energy cost of the excitons is distributed over many valleys so its stability is correspondingly enhanced. In consequence, high density *electron-hole droplets* (Fig. 6) form spontaneously - and can also be manipulated by applied elastic strain (Jeffries and Keldysh, 1983).

Coherence and Bose-Einstein condensation

Because excitons are light-mass bosons (albeit composite), there has also long been interest to observe Bose-Einstein condensation of excitons. In order to explore such physics, one needs to lower the temperature below the point where the thermal de Broglie wavelength exceeds the interparticle spacing, i.e. a temperature $k_B T_o = \hbar^2 n^{2/3} / M$. Among the systems studied are Cu_2O (which has long-lived excitons that are dipole forbidden), CuCl (which has very stable biexcitons) and two-dimensional quantum wells (in which

the electrons and holes can be physically separated). Such a state would be interesting not just for its statistical physics, but also because of the presence of spontaneous phase coherence, as in superfluid He, or cold atomic condensates (Moskalenko and Snoke, 2000).

While it has proved possible to enforce or encourage coherence through optical means, evidence for Bose-Einstein condensation of excitons in thermal equilibrium is still meager, though it is well-established for a closely-related composite particle that is a superposition of an exciton and a photon (Proukakis et al., 2017).

Optical properties

As discussed above, one of the principal reasons that excitons are so evident is because of their strong effects on the optical properties of solids. For very localized Frenkel excitons, it is largely correct to think of excitons as being atomic or molecular species, localized on specific sites in the solid. In general, it is not simple to calculate optical properties of excitons, except for the specific (and fortunately rather common) case of the hydrogenic Wannier exciton.

Dipole coupling

We consider here only the common case where the conduction and valence bands are of relative odd parity (as in zincblende II–VI and III–V semiconductors) so that the dipole matrix element

$$p_{cv} = \langle \psi_{ck} | \mathbf{e} \cdot \hat{\mathbf{p}} | \psi_{vk} \rangle_{k=0} \quad (6)$$

is non-zero and in a cubic system independent of the polarization direction $\mathbf{e}$. The probability P per unit time and per unit volume that an electromagnetic wave with a vector potential $A\mathbf{e}e^{i\omega t - \mathbf{q} \cdot \mathbf{r}}$ will be absorbed to create an exciton is given by the *Elliott formula* (Elliott, 1957).

$$P = \frac{4\pi}{\hbar} \left(\frac{eA}{m} \right)^2 |p_{cv}|^2 f(0)^2 \delta(E_{ex} - E_0 - \hbar\omega). \quad (7)$$

where we have assumed that the wavelength of light is long enough so that we may set $\mathbf{q} = 0$.

The answer is a sequence of lines at the energies $\hbar\omega_n = E_0 - Ryd^*/n^2$ corresponding to the principal quantum numbers $n = 1, 2, 3, \dots$, their intensities depending on the relative wavefunction $f(r)$ evaluated at the origin (when the electron and hole are coincident). Thus the absorption is largest if the exciton is tightly bound (since $f(0)^2 = 1/\pi(a^*n)^3$) and also if the basis states supporting the Bloch states are strongly dipole active. Eq. (7) gives only the Rydberg series below the continuum, but above and close to the edge of the continuum absorption, the excitonic effects enhance the absorption above that to be expected in free electron theory, as shown in Fig. 7.

Exciton polaritons

A peak in the absorption such as shown in Fig. 7 corresponds to a pole in the real part of the dielectric function, so below the gap,

$$\epsilon(\omega) \approx \epsilon_\infty + \frac{A_n}{\omega_n - \omega}, \quad (8)$$

where the amplitudes A_n are proportional to the coefficients in eq. (7). A pole in the dielectric response is a free mode of oscillation of the polarization; when light travels in a polarizable medium such as this the coupled modes are called *polaritons*. These modes can be made beautifully visible by confining the light between mirrors to form a planar microcavity. See Fig. 8.

Fig. 7 Absorption predicted by the Elliott formula of eq. (7). Notice that even above the continuum edge at E_0 the absorption (gray) is enhanced over that predicted in the absence of Coulomb interactions (solid line).

Fig. 8 Dispersion of two-dimensional microcavity polaritons. (a) Light is confined between two planar mirrors so as to fix the perpendicular momentum and to give a dispersion $\omega = \sqrt{\omega_0^2 + c^2 k^2}$ where k is the momentum parallel to the plane. $\omega_0 \approx c\pi/L$ where L is the separation between the mirrors, and this can be chosen to be resonant with the exciton energy as in the figure (A). On the scale of the wavelength of light, the exciton dispersion is negligible. The mixing of the two modes gives rise to level repulsion, and the dispersion marked by the solid points. (b) This dispersion is derived from the lower figure, which shows the luminescence from the microcavity as a function of angle, which can be directly converted into the parallel momentum k . Reproduced with permission from Houdre R, Weisbuch C, Stanley RP, Oesterle U, Pellandini P, and Illegems M (1994) *Physical Review Letters* 73: 2043.

Polaritons have been seen to spontaneously condense into a phase coherent state as a Bose-Einstein Condensate (Kasprzak et al., 2006).

For excitons that are strongly localized and thus subject to disorder and incoherent fluctuations, one rarely observes fully coherent modes. But nevertheless the resonant process that transfers an exciton from one localized state to a resonant one nearby can be important, in a process called *Förster transfer*.

Conclusion

This article has provided an elementary introduction to the physics of the most elementary electronic excitation in an undoped semiconductor. The exciton controls the observed optical spectrum, and exciton recombination is the source of light emission in lasers and light-emitting diodes. Exciton physics is also important for - and usually detrimental to - the performance of solar cells. So while the basic phenomena have been long understood, there continues to be considerable research activity to optimize materials for practical function, and also to exploit the collective behavior of excitonic matter for novel electrooptical devices.

Abstract

Polarons are composite quasiparticles comprising electronic charge carriers taken together with the alterations they induce in surrounding condensed matter. Strong-coupling polarons form when electronic charge carriers become 'self-trapped:' bound within potential wells stabilized by carriers' presence. Distinctively, exciting these bound carriers generates broad absorption bands. Strong-coupling polarons are slow and massive since moving them requires atomic motion. Their transport differs qualitatively from that of conventional electronic charge carriers. Large strong-coupling polarons move coherently with mobilities that fall with rising temperature. These massive quasiparticles' very weak scatterings by phonons produce much lower room-temperature mobilities than those permitted of conventional electronic charge carriers. Moreover, the long scattering times associated with large polarons' weak scattering relegates their principal ac (Drude) transport to below phonon frequencies. Small strong-coupling polarons move incoherently with even lower thermally assisted mobilities. Strikingly, a magnetic field often deflects small polarons in the opposite sense than it does conventional charge carriers, thereby producing anomalously signed Hall Effects. In exceptional circumstances charge carriers self-trap in pairs thereby forming large and small bipolarons. Some transport features distinguish them from polarons. Interference between carrier-induced atomic displacement patterns produce attractive interactions between like-charged polarons and short-range repulsive interactions between oppositely charged polarons.

Key points

- An electronic carrier is self-trapped when it is bound in a potential well produced by atoms assuming displaced equilibrium positions stabilized by the carrier's presence.
- Displaced distant ions generate the potential well which binds a large strong-coupling polaron's multi-site self-trapped carrier. Displacements of nearby atoms create the potential well which drives the collapse of a small strong-coupling polaron's self-trapped carrier to a single site. Disorder fosters small-polaron formation.
- Unusual transport and optical properties of large and small polarons distinguish them from each other and from conventional electronic carriers.
- Polarons tend to form in unusually complex materials. Polarons' distinctive properties enable unexpected applications.

Introduction

Adding electronic charge carriers to condensed matter generally affects its atoms' motion. A polaron is defined as the composite quasiparticle composed of an electronic carrier plus the altered atomic motion its presence induces.

There are two regimes in which polaron effects have been studied. In the weak-coupling regime, the relaxation of the electronic charge carrier in response to atomic movements only alters their frequencies. An electronic carrier then lowers the ground-state energy of the interacting system by a modest amount that vanishes as atomic vibrations are suppressed. Much larger energy shifts occur in the strong-coupling regime. Then the electronic carrier is 'self-trapped:' bound within the potential well produced by carrier-induced shifts of atoms' equilibrium positions. A dynamically stable strong-coupling polaron forms when the binding energy of the self-trapped electronic carrier greatly exceeds the characteristic phonon energy. Carrier-induced reductions of the frequencies with which atoms vibrate about their displaced equilibrium positions then make subsidiary contributions to a strong-coupling polaron's energy.

Unlike weak-coupling polarons, strong-coupling polarons have electronic and optical properties which distinguish them from conventional electronic charge carriers. Henceforth, this article will only consider strong-coupling polarons.

Self-trapping, the distinctive feature of strong-coupling polarons, is a nonlinear phenomenon. The potential well within which a self-trapped electronic carrier is bound results from atoms' assuming displaced equilibrium positions. However, these displacements of atoms' equilibrium positions are driven by the presence of the bound electronic carrier. That is, the potential well which binds a strong-coupling polaron's electronic carrier depends on its wavefunction. Solution of the carrier's nonlinear wave-equation generally permits two distinct types of strong-coupling polaron. A large-polaron's self-trapped carrier extends over multiple structural units. By contrast, a small-polaron's electronic carrier collapses to its minimal volume, e.g., a single structural unit.

A polaron's formation is governed by the forces between its electronic charge carrier and surrounding displaceable atoms. These interactions are often termed electron-lattice or electron-phonon interactions. A large polaron's formation usually requires long-range Coulomb-based interactions (e.g., the Fröhlich interaction) between its electronic carrier and condensed-matter's distant displaceable ions. By contrast, a small polaron's formation is usually generated by the energy of its electronic carrier depending on separations between the atoms it contacts. Separate large-polaron and small-polaron solutions can occur in the general case in which the electron-phonon interaction is the sum of long-range and short-range components.

The ratio of the static to optical dielectric constant, $\epsilon_0/\epsilon_\infty$, measures the prevalence of displaceable ions within a semiconductor. In particular, a ratio comparable to 1 indicates a covalent material with its purely short-range electron-phonon interaction. By contrast, ratios greater than or comparable to 2 (the value typifying alkali halides) indicate sufficiently displaceable ions to support the long-range electron-phonon interaction required for large-polaron formation. Ratios that greatly exceed 2 open the possibility of exceptional polaron effects, such as self-trapped carriers pairing to thereby form bipolarons.

A large polaron's self-trapped electronic carrier extending over multiple sites insures that its motion between adjacent sites is also coherent. Unlike the coherent transport of a conventional electronic charge carrier, a large polaron's motion is contingent on the movement of atoms. Therefore, a large polaron's motion is orders-of-magnitude slower and its effective mass is orders-of-magnitude greater than those of conventional electronic charge carriers. As a result, coherent large-polaron transport occurs with much lower mobilities than can be ascribed to conventional electronic charge carriers. In particular, the minimum mobility possible for a carrier's coherent transport occurs when its mean-free-path falls to its diameter, its de Broglie wavelength. This value is $qh/m_c kT$, where q and m_c denote the magnitudes of a carrier's charge and effective mass, T represents the absolute temperature while h and k respectively signify the Planck and Boltzmann constants. This minimum mobility is $300 \text{ cm}^2/\text{V-s}$ at room temperature for a carrier with a free electron's charge and mass. Thus, smaller room-temperature mobilities than this are inconsistent with the transport of conventional electronic charge carriers. However, such small mobilities are compatible with those of large polarons. For example, the mobility of a large polaron scattered by acoustic phonons is $qc_s R_{lp}/kT$ above a fraction of the Debye temperature, where c_s denotes the sound velocity and R_{lp} represents the large-polaron radius.

The distinctively extreme localization of a small-polaron's self-trapped carrier generates incoherent charge transport. Small polarons then move by successions of jumps between sites. The resulting small-polaron mobility is extremely small, $\ll 1 \text{ cm}^2/\text{V-s}$, and rises with increasing temperature. This thermally assisted hopping is Arrhenius above a significant fraction of the characteristic phonon temperature. A small-polaron's mobility manifests a progressively weaker temperature dependence as the temperature is lowered below this characteristic phonon temperature.

Large and small polarons also manifest optical properties which distinguish them from one another and from conventional electronic charge carriers. Unlike conventional charge carriers, large and small polarons both generate very broad asymmetric absorption bands that peak at energies well above phonon energies. A large-polaron's broad absorption band is generated by photo-ionizing its self-trapped electronic charge carrier from the potential well within which it is bound. With increasing photon energy, a large-polaron absorption band rises toward its peak and diminishes more slowly thereafter. A small-polaron's absorption of a photon induces its self-trapped carrier to hop. Each absorbed photon produces a small-polaron jump. With rising temperature, increased atomic vibrations increase the ranges of initial and final-state electronic energies involved in these photo-induced transitions. The width of a small-polaron absorption band is thereby thermally broadened. With increasing photon energy, a typical small-polaron absorption band rises toward its peak and then diminishes relatively rapidly. Thus, the thermally broadened asymmetry of a small-polaron absorption band distinguishes it from a large-polaron absorption band.

Large-polarons' coherent motion also produces an absorption analogous to the Drude absorption of conventional electronic charge carriers. Distinctively, a large polaron's huge mass causes it to be only very weakly scattered by ambient phonons that reflect off its softened atomic vibrations. As such, a large-polaron's motion is characterized by an extremely long relaxation time (proportional to its mass) that limits its Drude-like contribution to below the characteristic phonon frequency. Thus, there is a pseudo-gap in a large-polaron's absorption spectrum between its very low-frequency Drude-like absorption and the onset of its

broad high-frequency photo-ionization band. This pseudo gap opens with decreasing temperature as phonon scattering is progressively suppressed.

General features governing the formation and properties of strong-coupling polarons were succinctly described in this introductory section. However, other dramatic manifestations of the formation and transport of strong-coupling polarons rely on specific features of the condensed matter in which they form. For example, the controlled imposition of disorder can induce charge carriers' abrupt transformation between their being conventional charge carriers or large polarons and being small polarons. Unlike conventional carriers, small-polarons often form in materials whose local site arrangements generate Hall Effect sign anomalies. Small polarons are then deflected by a magnetic field in the opposite sense to that of free particles bearing the same charge. The self-trapping of holes on oxides' oxygen-related states transfers electrons to surrounding cations. As such, formation of such polarons can alter magnetic moments of surrounding magnetic cations. Special features emerge in materials containing especially displaceable ions as manifested by exceptionally large ratios of their static to high-frequency dielectric constants. These situations favor attractive interactions among large polarons inducing their pairing into bipolarons. Furthermore, a gas of large bipolarons can even condense into a large-bipolaron liquid. Short-range repulsive interactions between polarons of opposite charge suppress their recombination thereby increasing the lifetimes of optically induced polarons. These and other topics will be addressed in the following sections.

Long-range electron-phonon interactions

Polaron effects address the responses of electronic charge carriers to the comparatively slow movements of condensed-matter's relatively massive atoms. These responses are driven by electron-phonon interactions. Electron-phonon interactions arise from dependences of an electronic charge carrier's potential energy on the positions of the nuclei of the atoms within which it is immersed.

An electronic carrier's Coulomb interactions with ions that surround it generate a long-range component of its electron-phonon interactions. A simple model for the long-range component considers only ions that are outside of the electronic carrier's radius. Treating the condensed medium as a continuum, the polarizability associated with displacing nuclei is represented as the difference between the continuum's net polarizability and that due to its bound electrons. As such, the effective coupling constant considers a Coulomb interaction modified by the factor $1/\epsilon_\infty - 1/\epsilon_0$, the difference between the reciprocals of the high-frequency dielectric constant ϵ_∞ and the static dielectric constant ϵ_0 . This model's coupling strength is the Fröhlich constant, $\alpha \equiv e^2(1/\epsilon_\infty - 1/\epsilon_0)/(m_e/2\hbar^3\omega)^{1/2}$, where e and m_e respectively denote the electronic carrier's charge and effective mass with ω signifying an optic-mode atomic vibration frequency. This continuum theory addresses a very large-radius self-trapped state with $\alpha^2 \hbar\omega$ essentially being its binding energy. This model has been applied to self-trapped electrons in alkali halides.

Electrons in polar liquids such as water and ammonia are self-trapped. In these instances, the liquids' polar molecules are oriented to produce the potential well which binds the self-trapped electrons. Thus, for example, water molecules' electropositive hydrogen atoms are closer to the self-trapped electron than are their electronegative oxygen atoms.

Short-range electron-phonon interactions

The electron-phonon interaction in covalent semiconductors, termed the deformational-potential, is short-range. In particular, a charge carrier's energy depends on the separations between the atoms linked by the bonding or anti-bonding state that it occupies. The dependence of an electronic carrier's energy on the inter-atomic separation is typically quite large, 2–3 eV/Å. For comparison, the Coulomb interaction between two elementary charges separated by 3 Å is less than 5 eV even when the reduction associated with the dielectric constant (12 and 16 in Si and Ge, respectively) is ignored.

The short-range electron-phonon interaction's effect on an electronic state is inversely proportional to the number of atoms or bonds it contacts. Thus, for example, the electron-phonon interaction in a covalent semiconductor has a very much smaller effect on a large-radius donor state (e.g., a P donor state in Si) than it does on a well-localized donor state. Similarly, the effect of the short-range electron-phonon interaction on an electronic carrier in a molecule tends to decrease as its size increases.

A short-range electron-phonon interaction can predominate even in ionic solids such as alkali halides. For example, a hole in the alkali halide KCl is shared between two nearest-neighbor Cl anions to produce the molecular anion $(\text{Cl}_2)^{\cdot-}$: $\text{hole} + 2\text{Cl}^- \rightarrow (\text{Cl}_2)^{\cdot-}$. In other words, this self-trapped hole is severely localized in the chemical bond which forms between two displaced Cl anions.

Charge transfer between oxygen anions and surrounding cations generates a distinctive short-range electron-phonon interaction. Despite an isolated oxygen atom only having an electron affinity for one electron, oxygen anions are widely represented as having an oxidation state of –2. That is, the cations that typically surround an oxygen anion in a solid facilitates its accommodating an extra electron. This electron will leave an oxygen anion as surrounding cations are displaced away from it.

Cations in ionic solids sometimes possess magnetic moments. Without charge carriers, super-exchange between these magnetic cations usually drives these solids to form anti-ferromagnetic insulators. Dopants and defects can introduce charge carriers. Intra-atomic exchange interactions between charge-carriers' spins and the cations' magnetic moments foster their ferromagnetic alignment. A carrier-induced ferromagnetic cluster within an antiferromagnetic is termed a magnetic polaron. Although the electronic carrier bound within a prototypical magnetic polaron (e.g., an electron in EuTe) may be only mildly localized, electron-phonon interactions will increase its localization.

Self-trapping: Formation of a strong-coupling polaron

A strong-coupling polaron is defined by having its electronic charge carrier self-trapped. A self-trapped electronic carrier is bound within the potential well generated by surrounding atoms assuming equilibrium positions consistent with the electronic carrier occupying its bound state. Moving such a polaron requires displacing atoms from their carrier-induced equilibrium positions. The validity of this approach is generally taken to require that the binding energy of the self-trapped electronic carrier $-E_{st}$ exceed the phonon energy characterizing associated atoms' vibrations $\hbar\omega$.

The carrier-induced displacements of atoms' equilibrium positions are found by minimizing the Born-Oppenheimer adiabatic potential. This potential energy is the sum of (1) the potential energy associated with displacing atoms from their carrier-free equilibrium positions plus (2) the electronic energy as a function of atoms' positions. The adiabatic potential with atoms at these displaced equilibrium positions establishes the potential well within which an electronic carrier is self-trapped.

The chemistry underlying these interactions can be complex. Nonetheless, here, as is typical, electronic-carrier's energies and inter-atomic strain energies are simply modelled to respectively have linear and quadratic dependences on atoms' displacements from their carrier-free equilibrium values.

A general approach to self-trapping proceeds by treating the solid as a deformable continuum. The ground-state wave function for the self-trapped electronic carrier $\varphi(\mathbf{r})$ with energy E_{st} is then the solution of the non-linear wave equation:

$$\left[\frac{-\hbar^2}{2m_e} \nabla_r^2 - \frac{1}{S} \int d\mathbf{r}' |\varphi(\mathbf{r}')|^2 \int d\mathbf{u} F(\mathbf{r}-\mathbf{u}) F(\mathbf{r}'-\mathbf{u}) \right] \varphi(\mathbf{r}) = E_{st} \varphi(\mathbf{r}). \quad (1)$$

Here m_e denotes the electronic carrier's effective mass and S represents the continuum's stiffness constant per unit volume. The electron-phonon force per unit volume $F(\mathbf{r}-\mathbf{u})$ describes how the electronic potential energy at location $\mathbf{r}$ depends on a fiducial deformation of the continuum at location $\mathbf{u}$.

This non-linear wave equation can be utilized to express the self-trapping energy as a functional of its wavefunction. This functional is then recognized to depend simply on the dimensionless radius R of the self-trapped electron's normalized wavefunction. For a charge carrier which can move among sites with dimensionality d embedded within a three-dimensional ionic medium:

$$E_{st}(R) = \frac{T_e}{R^2} - \frac{2V_S}{R^d} - \frac{2V_L}{R}. \quad (2)$$

Here T_e , V_S and V_L are constants related to the self-trapped electronic carrier's kinetic energy and contributions to its potential energy from the short-range and long-range components of its electron-phonon interaction. Finally, the polaron energy $E_p(R)$ is obtained by combining $E_{st}(R)$ with the strain energy required to establish the potential well which binds the electronic charge carrier:

$$E_p(R) = E_{st}(R) + V_{strain}(R) \equiv \frac{T_e}{R^2} - \frac{V_S}{R^d} - \frac{V_L}{R}. \quad (3)$$

To obtain this result the strain potential energy $V_{strain}(R)$ is recognized as the sum of components from the same regions that contribute V_S and V_L . Here, for our simple model, each of these contributions is positive with half of the magnitude as that in Eq. (2).

This formula for the polaron binding energy in a continuum model is now augmented by a boundary condition. This boundary condition acknowledges that a self-trapped electronic carrier can shrink to no smaller than a minimal structural unit (e.g., ion, atom, bond or molecule). This effect is mimicked by choosing R to be the self-trapped electronic state's radius divided by its value when confined to a single structural unit. Thus our formula only applies for $R \geq 1$.

A minimum of $E_p(R)$ at a finite-radius gives the energy of the strong-coupling polaron in terms of T_e , V_S and V_L . However, essential features of polaron formation can be elucidated without knowing details. In particular, polaron formation depends critically on the range of the electron-phonon interaction and on the dimensionalities of (1) the electronic-carrier's motion and (2) the medium within which it is immersed.

Fig. 1 compares $E_p(R)$ plotted against R for a covalent material ($V_L \rightarrow 0$) with the electronic carrier being (a) unconstrained ($d = 3$), (b) constrained to a plane ($d = 2$), (c) confined to a chain ($d = 1$). For $d = 3$ the only possible finite-radius minimum is at

Fig. 1 (A) The effect of electronic dimensionality d on adiabatic self-trapping with a pure short-range electron-phonon interaction. Either a metastable or stable small-polaron state coexists with a free-carrier state when $d = 3$. (B) Only a stable small-polaron state or a free-carrier state is permitted when $d = 2$. (C) A stable self-trapped state, illustrated here as a large polaron, always exists when $d = 1$.

$R = 1$ indicating formation of a small polaron when $V_S > 2T_e/3$. The small polaron is either metastable ($T_e > V_S > 2T_e/3$) or stable ($V_S > T_e$) with respect to the carrier remaining free. Shrinking of a the electronic carrier from $R = \infty$ to $R = 1$ necessitates overcoming the "barrier to self-trapping," $4T_e^3/27V_S^2$. For $d = 2$ the electronic carrier will severely self-trap ($R = 1$) when $V_S > T_e$ thereby forming a small polaron. Alternatively, the carrier will remain free when $V_S < T_e$. For $d = 1$ there is a single finite-radius minimum. For $V_S < 2T_e$ this minimum is at $R = 2T_e/V_S$ corresponding to the formation of a large polaron with energy $-V_S^2/4T_e$. For $V_S > 2T_e$ the minimum is at $R = 1$ corresponding to the formation of a small polaron. Thus, the requirement for stable small-polaron formation becomes more stringent as the electronic dimensionality is decreased: $V_S > T_e$ for $d = 3$ or 2 while $V_S > 2T_e$ for $d = 1$.

Although idealized systems of diminished electronic dimensionality are studied, their realization may be difficult to achieve. In particular, investigations of quasi-one-dimensional systems find that extreme anisotropies are required to achieve the idealized $d = 1$ limit.

Short-range interactions between a carrier and the atoms it contacts are presumably ubiquitous. In this sense, models with only a long-range interaction with displaceable ions are artificial. Moreover, we have already established general features of such polarons. In particular, examination of the above equation for $E_p(R)$ shows that the case of a carrier within a three-dimensional ionic medium without short-range electron-phonon interactions ($V_S = 0$) is isomorphic to the $d = 1$ case with a pure short-range interaction ($V_L = 0$) that was discussed above.

Estimates of V_S obtained from experiments and computations range from over several tenths of an eV to several eV. Meanwhile, V_L is essentially the Coulomb repulsion between two elementary charges confined to a single site, ≈ 10 eV, multiplied by the factor $[(1/\epsilon_\infty) - (1/\epsilon_0)]/2$. Without displaceable ions this factor is near zero. By contrast, for an alkali halide, a prototypical ionic solid, this factor rises to about 0.1.

Combining short-range and long-range components of the electron-phonon interaction can produce several distinct self-trapping scenarios. Consider a three-dimensional model in which the long-range interaction generated by displaceable ions is progressively added to a modest short-range interaction which by itself is presumed to be too weak to produce even a metastable self-trapping, $V_S < 2T_e/3$. Fig. 2 plots $E_p(R)/T_e$ for progressively increasing values of V_L . Curve *a*, for $V_L = 0$, shows no self-trapping. Curve *b* shows an increase of V_L introducing an energetically stable large-polaron state at $R = 2T_e/V_L$ along with a metastable small-polaron state at $R = 1$. Curve *c* shows a further increase of V_L stabilizing the small-polaron state with respect to the large-polaron state. Finally, curve *d* shows the collapse of the large-polaron state into the small-polaron state when $3V_LV_S > T_e^2$.

Atoms generally vibrate about their carrier-induced displaced equilibrium positions. The stiffness constants governing such vibrations are found from the second derivatives of the adiabatic potential with respect to atomic displacements evaluated at their carrier-induced equilibrium position. The stiffness linking positions u and u' is reduced by the polarization of a self-trapped carrier as it adjusts to alterations of its self-trapping potential well induced by atomic vibrations. Thus, a self-trapped carrier is generally associated with both (1) displacements of the equilibrium positions of surrounding atoms and (2) softening of the stiffness constants governing their vibrations. Carrier-induced softening of atoms' vibrations reduces their frequencies and thereby lowers a polaron's free energy. For simplicity, this contribution to polaron stability has heretofore been neglected in our discussion of the formation of strong-coupling polarons. Nonetheless, carrier-induced softening is central to large-polarons' transport.

Large- and small-bipolaron formation

Charges in solids often pair as singlets. A two-center covalent bond forms as an electron shifts from each of two atoms to being centered between them. Concomitantly, the two atoms move toward one another. The two electrons then overcome their mutual

Fig. 2 Addition of the long-range component of the electron-phonon interaction facilitates self-trapping. (a) No self-trapped state with $V_L = 0$. Progressively increasing V_L introduces (b) metastable small-polaron state with stable large-polaron state and then (c) stable small-polaron state with metastable large polaron state. (d) Large-polaron state collapsing yields only a stable small-polaron state.

Coulomb repulsion as each of them benefits from its attraction to the bond's two atoms. Similarly, electronic charge carriers can doubly occupy a self-trapping potential well to form a strong-coupling singlet bipolaron.

The model developed to address formation of a strong-coupling polaron can be extended to address the formation of a singlet bipolaron. A bipolaron's two uncorrelated self-trapped electronic carriers each benefits from their doubling of their carrier-induced displacements of atoms' equilibrium positions. Thus, both short-range and long-range contributions to the polaron potential energy are augmented four-fold, $4 = 2 \times 2$. Meanwhile the Coulomb-repulsion between the two self-trapped electronic carriers is reduced by the high-frequency dielectric constant ϵ_∞ , associated with electronic polarization of the medium. Thus, the energy of a bipolaron $E_{bp}(R)$ becomes:

$$E_{bp}(R) = \frac{2T_e}{R^2} - \frac{4V_S}{R^d} - \frac{4V_L}{R} + \frac{U}{\epsilon_\infty R} = 2E_p(R) + \frac{U}{\epsilon_0 R} - \frac{2V_S}{R^d}. \quad (4)$$

The bipolaron energy is then compared with that of two well-separated polarons $2E_p(R)$ where it has been noted that the long-range component of the electron-phonon interaction V_L is simply related to the bare Coulomb interaction between a pair of charges on a minimal structural unit U : $V_L = [(1/\epsilon_\infty) - (1/\epsilon_0)]U/2$.

The final two terms on the right-hand side of this equation describe the essential physics of bipolaron formation. Bipolaron formation is energetically favorable when the paired carriers' residual mutual Coulomb repulsion, $U/\epsilon_0 R$ is overwhelmed by the additional binding provided by the short-range electron-phonon interaction, $2V_S/R^d$. In particular, large-bipolaron formation, $R > 1$, is fostered in systems whose electronic carriers have reduced dimensionality.

Bipolaron formation on an embedded plane, $d = 2$, is investigated by comparing the minima of $E_{bp}(R)$ and $2E_p(R)$ with respect to R . A planar large-bipolaron will form if the minimum of $E_{bp}(R)$ occurs at $R > 1$ with a lower energy than the minimum value of $2E_p(R)$. In particular, a planar large-bipolaron can form if

$$\frac{4(\epsilon_0/2\epsilon_\infty) - 3}{2(\epsilon_0/2\epsilon_\infty)^2 - 1} \leq \frac{2V_S}{T_e} \leq 1. \quad (5)$$

Thus, the value of V_S that drives large-bipolaron formation must be large enough to foster its energetic stability without being so large as to collapse the large bipolaron into a small bipolaron. These requirements can be met in unusual circumstances where $\epsilon_0/2\epsilon_\infty$ rises above 1.

Cuprates are prime candidates for large-bipolaron formation because (1) their charge carriers are confined to CuO_2 planes, $d = 2$, that are (2) embedded within media with exceptionally displaceable ions, $\epsilon_0 \gg 2\epsilon_\infty \gg 1$. An hypothesized microscopic model (Emin, 2017) envisions a large-bipolaron's paired holes in a CuO_2 plane of p-doped antiferromagnetic La_2CuO_4 occupying out-of-plane non-bonding oxygen orbitals. As depicted in Fig. 3, the core of such a large-bipolaron hole removes two electrons from the four contiguous O^{2-} anions thereby shifting their equilibrium positions inward while shifting the equilibrium positions of the four surrounding Cu cations outward. Concomitantly, electrons transferred from the four oxygen anions to the four copper cations convert each of them from a spin- $1/2$ Cu^{2+} to a spin-less Cu^{1+} . Such large-bipolarons thereby eliminate the doped material's magnetism. Two electrons then remain distributed over the out-of-plane orbitals of the four oxygen anions: $2 \text{ holes} + 4\text{O}^{2-} + 4\text{Cu}^{2+} \rightarrow (\text{O}_4)^{2-} + 4\text{Cu}^{1+}$. The lowest-frequency largest-amplitude optic-mode type radial vibration of these ions has d -symmetry.

Boron carbides' high-density of low-mobility hopping-type charge carriers appear to pair as singlet small bipolarons since they do not contribute unpaired spins to its magnetic susceptibility (Emin, 2006). Paired carriers' small mutual Coulomb repulsion results from their being constrained to the surface of spheroidal boron-rich 12-atom icosahedra in a material with a large electronic polarizability, $\epsilon_\infty \gg 1$.

Fig. 3 Removing two electrons from four contiguous oxygen anions (large open circles) of the basic structural unit of a CuO_2 plane shifts their equilibrium positions inward and those of the copper cations (smaller filled circles) outward.

Disorder-induced small-polaron formation

There is a qualitative dichotomy between states that are only minimally affected by electron-phonon interactions and small-polaronic states. Moreover, rough estimates of the pertinent constants indicate many situations that are close to the boundaries between these two radically different situations.

Disorder, by increasing the localization or slowing of charge carriers, can trigger their collapse into small polarons. Different models (c.f., [Further reading](#)) have been employed to illustrate these effects.

One approach envisions disorder generating potential wells that confine charge carriers. In particular, disorder is presumed to introduce contributions to the adiabatic potential of the form $-V_{\text{disorder}}/R^n$. Electron-phonon interactions then synergistically enhance carriers' localization. As a carrier's disorder-induced localization is progressively increased, it ultimately abruptly collapses into a small-polaron, confining a carrier to a single structural unit. The situation is analogous to that portrayed in [Fig. 2](#), in which a progressively stronger long-range component of the electron-phonon interaction, $-V_L/R$, ultimately drives a carrier's collapse into a small polaron.

An explicit example considers the abrupt collapse of a large-radius donor state in the ferromagnetic semiconductor EuO. The donor electron moves between Eu cations' $S = 7/2$ spins. The intra-atomic exchange I between the donor electron and each of the Eu cations it contacts fosters their alignment even as rising temperature drives misalignment of the spins of other Eu cations. As the temperature is raised toward the EuO Curie temperature, $T_C \approx 70$ K, the large-radius donor abruptly collapses to a small-radius donor. Concomitantly, the number of aligned Eu spins shrinks. The product of the temperature and the difference between the spin-misalignment entropy associated with large-radius and small-radius states is the transition's latent heat. The free-energy functional for this system is:

$$F_{\text{bnp}}(R, T) = \frac{\left[T_e - C\left(\frac{I}{kT_C}\right)kT\right]}{R^2} - \frac{V_S}{R^d} - \frac{(V_L + V_d)}{R}, \quad (6)$$

where C denotes a numerical constant which for EuO is estimated to be between 0.01 and 0.1 and V_d represents the electron's Coulomb attraction to its donor (e.g., a dopant or an oxygen vacancy). The minimum of this free-energy functional can collapse from that for a large-radius donor, $R \gg 1$, to that for a small-polaronic state, $R = 1$, as the temperature is raised above 50 K.

Strikingly, the magnetic disorder which drives this transition is controlled by the temperature and is therefore readily reversible. This collapse also can be reversed by applying a magnetic field which fosters alignment of the Eu cations' spins. In particular, the temperature of the collapse rises as the square-root of the applied magnetic field.

Disorder can also induce the self-trapping of freely moving electronic excitations. For example, excitons in crystalline TlCl or TlBr move freely while those in the mixed crystal $\text{TlCl}_x\text{Br}_{1-x}$ self-trap. Holes injected into crystalline orthorhombic sulfur appear to move with a moderate mobility which falls with increasing temperature until the crystal's softening temperature is reached. Then, once the crystal's S_8 molecules lose registry with one another, the mobility drops precipitously. As the temperature is raised further the mobility rises in an Arrhenius manner, typical of small polarons. Charge carriers in crystalline Si and Ge have large Hall mobilities that fall with increasing temperature. By contrast, the Hall mobilities of amorphous Si and Ge are very low, rise in an Arrhenius manner with increasing temperature and display the sign anomalies expected for both electron and hole small polarons.

Nearest-neighbor inter-atomic separation are nearly the same for crystalline and amorphous semiconductors. By contrast, amorphous covalent semiconductors have large ($>10^\circ$) variations of their bond angles. The electronic transfer energies of electrons in anti-bonding states and holes in bonding states are very sensitive to bond-angle variations.

The effect of transfer-energy variations on small-polaron formation is now considered. Self-trapping was previously addressed by determining whether an electronic carrier will be bound within the potential well generated by fixing surrounding atoms at their carrier-induced displaced equilibrium positions (the adiabatic limit). With just the ubiquitous short-range component of the electron-phonon interaction, an electronic carrier in a three-dimensional deformable continuum will either self-trap as a small-polaron or remain free.

An electronic carrier remains free if its energy band extends below the small-polaron energy. Disorder-induced transfer-energy variations by themselves can then introduce sites at which small-polaron formation is stable. Moreover, transfer energies emanating from such sites are suppressed since moving a self-trapped electronic carrier requires substantial movement of the associated atoms. Sites with stable small-polaron formation are thereby extended to some adjacent sites. Ultimately, through this nonlinear feedback mechanism, modest transfer-energy disorder can trigger global small-polaron formation. All told, transfer-energy disorder significantly reduces the electron-phonon coupling strength required to stabilize small-polaron states with respect to free-carrier states.

Such a small-polaron collapse requires transfer-energy variations (non-diagonal disorder) that are comparable to the small-polaron energy and the electronic carrier's bandwidth. By contrast, severe Anderson localization requires diagonal-disorder energies that are an order of magnitude greater than the electronic carrier's bandwidth, as envisioned for impurity conduction in very lightly doped compensated semiconductors.

Coherent and incoherent polaron transport

A strong-coupling polaron's motion requires shifting surrounding atoms away from the displaced equilibrium positions they assume when generating the potential well which binds its self-trapped electronic carrier. A self-trapped electronic carrier only moves in response to these atoms' movements.

In the most extreme case, atoms may move enough to completely eliminate the self-trapping potential well thereby liberating its electronic carrier. The electronic carrier can then move away until atoms elsewhere in the material bind it within another self-trapping potential well. This transport mode corresponds to free-carrier motion limited by occasional self-trapping.

Transport of a strong-coupling polaron occurs when the centroid of its self-trapped electronic carrier moves between sites in response to atoms' movements shifting the potential well that binds it. The motion of a strong-coupling polaron is regarded as coherent when its self-trapped electronic carrier extends over multiple sites. As such, the self-trapped electronic carrier of a large polaron moves continuously in response to the classical motion of surrounding atoms. In particular, the mass for a three-dimensional large-polaron is $\approx E_p/(\omega R_p)^2$, where E_p and R_p respectively denote the polaron energy and radius while ω represents the frequency characterizing vibrations of the relevant atoms. The effective mass for a one-dimensional large-polaron interacting with acoustic phonons is $4E_p/c_s^2$, where c_s denotes the sound velocity. These polaron masses are generally orders of magnitude greater than the free-electron mass.

Since the huge masses of strong-coupling large polarons result from the requisite atomic motion, they can only be observed at frequencies below those characterizing atomic motion. By contrast, masses measured at high frequencies correspond to those of electronic charge carriers, e.g., an electronic carrier moving within the self-trapping potential well that binds it.

Distinctively, the transport of a small polaron is usually incoherent. Its severely localized self-trapped electronic carrier moves discontinuously between sites in response to atomic movements. Small-polaron transport is generally described as occurring via sequences of phonon-assisted hops.

It should be noted that a polaron in a crystal can equally well occupy any of its geometrically equivalent sites. Therefore, its eigenstates extend throughout the crystal. However, unlike purely electronic Bloch states, polaron eigenstates transfer the pattern of displaced atomic equilibrium positions collaterally with the self-trapped electronic carrier. Therefore, the width of such a polaron band is proportional to the product of the overlaps between each atom's vibrational wavefunction when its self-trapped electronic carrier is shifted between neighboring sites. For example, the maximum nearest-neighbor transfer energy associated with a small-polaron adiabatically shifted between adjacent sites with the electron-phonon interaction taken as purely short-range is

$$t_{sp} \cong \sqrt{\frac{E_p \hbar \omega}{\pi}} e^{-\left(\frac{E_p}{\hbar \omega}\right) \coth\left(\frac{\hbar \omega}{2kT}\right)}, \quad (7)$$

where the strong-coupling condition insures that $E_p \gg \hbar \omega$. It should be observed that t_{sp} is (1) very small, $t_{sp} \ll \hbar \omega$, (2) decreases with rising temperature, and (3) vanishes in the classical limit, $\hbar \rightarrow 0$. The extreme narrowness of a small-polaron band implies that its coherent motion associated with it will be suppressed by any realistic perturbations.

Large-polaron transport

The mobility μ of a coherently moving carrier of charge q can be schematically written in terms of the average of the product of its velocity v and its mean-free-path ℓ : $\mu = e \langle v \ell \rangle / kT$. The minimum mobility for coherent transport corresponds to the carrier mean-free-path falling to its size, its de Broglie wavelength $\lambda = h/p = h/m_c v$, where m_c denotes the carrier's effective mass: $\mu_{\min} = (eh/m_c kT)$. The minimum coherent-transport mobility associated with a carrier mass equal to the free-electron mass is about $300 \text{ cm}^2/\text{V-sec}$ at room temperature. Since this minimum mobility is inversely proportional to the carrier effective mass, room-temperature mobilities that are much lower than this minimum imply very large effective masses such as those of large polarons.

A large-polaron's transport depends critically on the phonon modes involved in constructing the potential well in which its electronic carrier is self-trapped. These modes are locally softened by relaxation of the large-polaron's self-trapped electronic carrier to their atoms' vibratory displacements. A large polaron's local softening of these vibrational modes impedes passage of the solid's indigenous phonons through it. This regional phonon softening is the origin of the scattering between a large polaron and ambient phonons.

The huge mass of a strong-coupling large polaron insures that its thermal momentum near room temperature exceeds that of the phonons with which it scatters. Thus, while conventional electronic charge carriers undergo wide-angle scattering by phonons, a large polaron primarily "reflects" incident phonons. This difference may manifest itself in a solid's carrier-induced thermal conductivity.

The dynamics of the scattering between a large polaron and a solid's phonons depends on the velocity with which vibrational energy can be transported through a solid. This feature of phonon transport is governed by their vibrational dispersion. Two examples illustrate contrasting limits. Acoustic phonons have substantial dispersion with the velocity of their longitudinal branch being just that of sound, c_s . Optic phonons are frequently represented as Einstein oscillators, which possess zero vibrational dispersion. Therefore, the huge mass of a large polaron causes it to move more slowly than the acoustic phonons which it scatters. However, a large polaron moves faster than Einstein oscillators that are static.

The scattering rate for a large polaron by acoustic phonons is

$$\frac{1}{\tau_{lp}} \cong \langle N_{ac} \sigma \left(\frac{2\hbar q}{m_{lp}} \right) \rangle \cong \frac{kT}{m_{lp} c_s R_p}, \quad (8)$$

where N_{ac} denotes the density of thermally available acoustic phonons, σ represents the cross-section for scattering between a large polaron and acoustic phonons, and the final factor is the change of a large polaron's velocity generated by its reflection of an

acoustic phonon of momentum $\hbar q$. The final expression on the right results from evaluating the average at or near room-temperature upon recognizing that the relevant phonons have wavelengths comparable to the polaron radius R_p . It is noteworthy that this scattering rate is inversely proportional to the large-polaron mass, m_{lp} . That is, a large polaron is not easily scattered by acoustic phonons which possess much smaller momenta.

A distinctive characteristic of a large polaron is its extremely long scattering time, $\tau_{lp} \approx (E_p/kT)/\omega \gg 1/\omega$. This feature manifests itself by the real part of the large-polaron conductivity as a function of applied frequency Ω , proportional to $1/(1 + \Omega^2\tau_{lp}^2)$, only being appreciable at frequencies well below the phonon frequency ω . Moreover, as will be discussed subsequently in the section on polaron's optical properties, a large polaron's conductivity also has a very broad peak beginning at frequencies well above that of its characteristic phonon. Thus, there is a pseudo gap between the low-frequency, $\Omega \ll \omega$, and the high frequency, $\Omega \gg \omega$, contributions to a large polaron's conductivity and related absorption. By contrast, a conventional electronic carrier's scattering time is very short, $\tau \ll 1/\omega$. Thus, the frequency dependence of the real part of a conventional electronic carriers' conductivity, its Drude conductivity, is appreciable at frequencies that are many orders of magnitude higher than that for a large polaron.

The large-polaron mobility corresponding to its long scattering time τ_{lp} and huge effective mass m_{lp} is:

$$\mu_{lp} \equiv e \frac{\tau_{lp}}{m_{lp}} = \frac{ec_s R_{lp}}{kT}. \quad (9)$$

This mobility is typically comparable to $1 \text{ cm}^2/\text{V-sec}$ at room temperature, much smaller than that for conventional electronic charge carriers.

This mobility's monotonic decrease with increasing temperature distinguishes it from that for a large polaron interacting with dispersion-less phonons, Einstein oscillators. The mobility arising from the scattering of a large polaron with Einstein optic vibrations involves a competition between two factors. First, the density of optic phonons increases with rising temperature. Second, the efficacy of their scattering of a large-polaron diminishes as its de Broglie wavelength decreases with increasing temperature. Strikingly, this effect is reported to make a large-polaron's mobility rise with increasing temperature above a small fraction of the optic-phonon temperature.

Small-polaron transport: Elemental hops

A small-polaron's severe localization renders its transport incoherent. This incoherent transport is best described as proceeding via successions of thermally assisted jumps. A small-polaron's hop is governed by movements of the atoms to which its self-trapped electronic carrier is coupled. The motions of these atoms are controlled by the system's adiabatic potential.

The processes governing an elemental small-polaron hop depends on its two-site adiabatic potential. A simple model has the portion of the adiabatic potential governing a jump depending on a single relative atomic configurational coordinate. A small-polaron hop then corresponds to motion of a fictitious particle with an appropriate reduced atomic mass moving between minima of this two-site adiabatic potential.

Fig. 4 shows the two-site adiabatic potential $V_{ad,2}(x)$ as a function of the relative atomic-configuration coordinate x . An energy barrier exists between equivalent minima located at x_i and x_f . A fictitious particle's occupation of one of these two equivalent minima corresponds to the self-trapped carrier occupying one of the two equivalent sites between which this small polaron can move.

At low temperatures the charge carrier moves from initial to final sites as the associated atoms undergo quantum-mechanical tunneling between the configurations they assume when the electronic carrier occupies corresponding initial and final sites. This relatively slow atomic tunneling process is depicted in Fig. 4 by the thin blue arrow passing through the thick portion of its energy barrier.

Fig. 4 The two-site adiabatic potential energy for a small-polaron hop is plotted against the relative atomic configurational coordinate x . The dashed line indicates the extension of the adiabatic potential for occupation of the initial site in the absence of electronic transfer to the hop's final site.

As the temperature is raised, the amplitudes of atoms' oscillations increase. The fictitious particle, the large black dot in Fig. 4, then rises higher in its potential well before tunneling through a relatively thin portion of this figure's energy barrier. The green arrow depicting this tunneling is thicker than that of the blue arrow to indicate that the tunneling rate increases as the width of the energy barrier decreases. The decrease in the energy barrier indicates reduced disparity of the positions of atoms involved in their quantum-mechanical tunneling.

At sufficiently high temperatures, the fictitious particle can move between potential wells by transcending the energy barrier rather than tunneling through it. The predominant small-polaron hopping process then does not involve atoms' tunneling. As indicated by the thickness of the red arrow the small-polaron jump rates exceeds that of processes requiring atomic tunneling.

Fig. 5 plots the elemental adiabatic small-polaron jump rate for a hop between equivalent sites. At high temperatures the jump rate is Arrhenius. Its activation energy corresponds to the energy difference between the minima of the adiabatic potential and the height of the energy barrier shown in Fig. 4. This activation energy is the minimum energy required to displace atoms from the equilibrium positions they assume when a hop's initial site is occupied so as to bring the electronic energies of the jump's initial and final sites into coincidence. As the temperature is lowered the small-polaron jump rate becomes non-Arrhenius. This behavior indicates the progressive freeze out of multi-phonon processes requiring the absorption of more energy than is the minimum consistent with the requirement of energy conservation. The details of these non-Arrhenius temperature dependences depend upon the particular phonons that are coupled to the electronic charge carrier. However, the transition between Arrhenius and non-Arrhenius behavior typically occurs at about one third of the characteristic phonon temperature.

The example presented here presumed that the sites between which hopping occurs are equivalent to one another, as they are in a perfect crystal. Nonetheless, except at very low temperatures, the adiabatic small-polaron jump rate between inequivalent sites is usually only modified by the factor $\exp(-\Delta/2kT)$, where Δ denotes the difference between final and initial sites. At extremely low temperatures the energy absorbed in a hop falls to the minimum energy consistent with energy conservation. Then the rate for a hop upward in energy is proportional to $\exp(-|\Delta|/kT)$ while that for a hop downward in energy is temperature independent.

A small-polaron's adiabatic jump rate's temperature dependence (e.g., its activation energy) implicitly measures the distances that atoms surrounding a jump's pair of sites must move to generate a hop. This effect depends on the range of an electronic charge carrier's electron-phonon interaction. Nonetheless, the temperature-dependence of a small-polaron's adiabatic jump rate generally increases as the separation between initial and final sites is increased. Thus, the activation energy for a hop increases with its distance. By itself, this effect favors short hops over longer hops.

Application of a dc electric field E alters the temperature dependences of the jump rates for hops emanating from a site. This effect is greatest for long jumps. The resulting effect usually increases the net jump rate from a site. Frenkel-Poole behavior denotes the applied electric-field E increasing the net jump rate from a site by the factor $\exp.[CE^{1/2}/kT]$, where C denotes a constant.

Arrhenius small-polaron hopping is adiabatic when its self-trapped electronic carrier readily moves between sites in response to atoms' movements establishing the requisite coincidence event. The magnitude of the electronic transfer energy t_{tr} must then exceed the energy spread $\Delta E_{dur} \approx [\hbar\omega(E_A kT)^{1/2}]^{1/2}$, determined by the Heisenberg uncertainty principle, associated with the establishment of an energy coincidence. Fig. 6 displays the probability P of a hop being adiabatic plotted against the ratio $t_{tr}/\Delta E_{dur}$.

For computational simplicity, initial studies of small-polaron hopping presumed that the inter-site transfer energy of an electronic carrier is so small that it rarely moves between sites even when atomic movements enable it to do so, $P \approx 2(t_{tr}/\Delta E_{dur})^2 \ll 1$. However, estimates of $t_{tr}/\Delta E_{dur}$ often imply adiabatic hopping, $P \approx 1$. Fortunately, the value of P can often be estimated from experiments. In particular, the pre-exponential factor for Arrhenius small-polaron hopping mobility is $(ea^2v/kT)P$, where a denotes the separation between small-polaron sites. In addition, the corresponding pre-exponential factor of the dc conductivity for thermally generated small polarons is $(e^2v/akT)P$. Typical estimates of the bracketed expressions in these two pre-exponential factors are respectively about $1 \text{ cm}^2/\text{V-sec}$ and 10^3 S/cm . The frequent observations of pre-exponential factors that are close to these values implies that their small-polaron hopping is adiabatic, $P \approx 1$.

Fig. 5 The rate for an elemental adiabatic small-polaron jump between equivalent states divided by the hop's characteristic phonon frequency ν is plotted versus $h\nu/kT$. The colored arrows correspond to those in Fig. 4 which indicate the processes which predominate in each temperature regime.

Fig. 6 The probability P of a self-trapped electronic carrier adiabatically moving between sites during a coincidence event is plotted versus $t_{tr}/\Delta E_{dur}$. The circle indicates the non-adiabatic regime where $P \propto t_{tr}^2$.

Small bipolarons also move by thermally assisted hopping. At low temperatures small-bipolarons move together as singlet pairs. However, at high temperatures pairs separate and charge transport becomes predominately that of small polarons. The activation energy for pair-breaking and subsequent small-polaron hopping is the sum of two contributions. The contribution from pair separation is half of the binding energy of the bipolaron with respect to forming two separate polarons, $(2E_p - U)/2$, where U represents a pair's on-site Coulomb repulsion. As before, the activation energy for small-polaron hopping is below $E_p/2 - t_{tr}$. Therefore the activation energy for breaking a pair and subsequent small-polaron hopping is less than $3E_p/2 - U/2 - t_{tr}$. By comparison, the activation energy for the pair jumping as a unit is $2E_p - t_{2tr}$, where t_{2tr} denotes the transfer energy for the paired electronic carriers moving as a unit in response to a coincidence event, $t_{2tr} \ll t_{tr}$. Thus, due to its smaller activation energy, high-temperature small-bipolaron transport is dominated by pair breaking. Distinctively, the paramagnetic susceptibility then garners a high-temperature Arrhenius contribution from the collateral generation of unpaired self-trapped electronic charge carriers. This phenomenon appears to occur in boron carbides, $B_{12+x}C_{3-x}$ with $0.15 < x < 1.7$, where $x/2$ denotes the fraction of unit cells with hole-like small bipolarons (Emin, 2006).

Small-polaron hopping is qualitatively different from very low temperature inter-impurity hopping conduction in lightly doped compensated crystalline semiconductors (e.g., P and B doped Si). The small doping concentrations (e.g., 10^{15} cm^{-3}) imply very long (e.g., 1000 Å) non-adiabatic jumps. The large dopant radii (e.g., 20 Å and 45 Å in Si and Ge, respectively) and small conductivity activation energies (e.g., 10^{-4} – 10^{-3} eV) imply each hop involves absorption or emission of only a single very long wavelength acoustic phonon. As such, the elemental jump rates are proportional to $\exp[-(\Delta + |\Delta|)/2kT]$ in the very low-temperature limit and proportional to T at higher temperatures. All told, inter-impurity hops are primarily non-adiabatic, proportional to t_{tr}^2 , and between sites whose near-random energies are determined by their proximity to the doped-semiconductors' charged impurity centers. Rates for individual inter-impurity hops therefore involve competitions between (1) transfer energies which favor short jumps and (2) energy absorptions which favor long jumps. By itself, these effects would lead to variable-range hopping. By contrast, small-polaron hops are usually short (<10 Å), adiabatic and multi-phonon. As such, small-polaron jump rates are non-Arrhenius below a fraction of the phonon temperature and Arrhenius at higher temperatures with activation energies between 0.1 and 1 eV.

Small-polaron relaxation phenomena

Small-polaron hopping involves local accumulation and dissipation of atoms' vibrational energy. In particular, the elemental thermally assisted small-polaron hop described in Fig. 4, begins as the amplitudes of atomic vibrations increase while the self-trapped electronic carrier occupies its initial site and ends with vibrational energy being dissipated to surrounding atoms after the electronic carrier transfers to its final site. Thus, the jump process involves vibrational dispersion.

Early studies of small-polaron hopping only explicitly addressed the actual inter-site transfer of an electronic charge carrier. The processes governing local accrual and subsequent dispersal of vibrational energy were ignored. Rather, the energies of local vibrations were assumed to retain their equilibrium distribution. This procedure is justified in the non-adiabatic limit since the probability of an electronic transfer in response to atoms assuming favorable configurations is then arbitrarily small. As such, dispersion-related transfers of atoms' vibrational energies are always fast enough to establish equilibrium prior to an electronic charge carrier transferring between sites. However, as noted earlier, small-polaron hopping is typically adiabatic. In this situation, the inter-site transfer of an electronic charge carrier occurs in less than a vibrational period while the accumulation and dissipation of vibrational energy is much slower. Transport of vibrational energy then affects small-polaron hopping.

Following a hop, vibrational energy is dissipated away from the involved sites. In a three-dimensional vibrational system, the time for the sites' vibrational energy to fall to $kT/2$ following a hop with activation energy E_A is $\tau_{\text{relax}} \approx (1/\Delta\omega)(2E_A/kT)^{2/3}$, where

$\Delta\omega$ denotes the spread of frequencies characterizing the phonons involved in the jump. This relaxation time will generally exceed that governing atoms' vibrations: $\omega\tau_{\text{relax}} \gg 1$, where $\omega \gg \Delta\omega$ and $E_A \gg kT$. Thus, relaxation from one hop may not be completed before vibrations establish another adiabatic jump. Hopping will then be correlated. Adiabatic small-polaron hops occur in flurries separated by dormant intervals. Within a flurry, the probability of back and forth hopping between a pair of sites is greatly enhanced while jumps to previously unvisited sites are also enhanced but to a lesser extent.

As shown in Fig. 4, a self-trapped electronic carrier's adiabatic over-the-barrier shuttling between a pair of sites is governed by the broad double-well adiabatic potential. By contrast, a carrier confined to the initial site is governed by the single harmonic potential depicted by the dashed curve. The difference in vibrational free energy between that with the carrier transferring back-and-forth and that with it confined to its initial site, $\Delta F_{\text{vib}} < 0$, augments the jump rate. The jump rate is also halved because the shuttling carrier only ends on the final site half of the time. The formula for the Arrhenius jump rate then becomes:

$$R_{M-N} = \left[\frac{v}{2} \exp\left(-\frac{\Delta F_{\text{vib}}}{kT}\right) \right] \exp\left(-\frac{E_A}{kT}\right) \rightarrow \left[\frac{v}{2} \exp\left(\frac{E_A}{t_{\text{tr}}}\right) \right] \exp\left(-\frac{E_A}{kT}\right), \quad (10)$$

where the final expression applies when $t_{\text{tr}}^2 > E_A kT$ (Emin, 2013). In accord with the observed Meyer-Neldel compensation effect, this expression has its temperature-independent factor increasing exponentially with the hopping activation energy E_A . The rise of the jump rate's temperature-independent factor with increasing E_A partially compensates for the decrease of the rate's thermally activated factor.

Electronic charge carriers injected into condensed matter must dissipate a significant amount of energy in the process of their becoming self-trapped. In particular, for an injected electronic carrier to form an equilibrated small polaron an energy at least comparable to its binding energy (greater than several tenths of an eV) must be transferred into the vibrations of associated atoms. The resulting very large athermal vibrations can facilitate establishing the energetic coincidences required for small-polaron hopping. Thus, transient hopping can occur without significant additional absorption of vibrational energy. As a result, transitory adiabatic small-polaron hopping will be nearly activation-less. It will occur with a mobility of about $ea^2v/kT \approx 1 \text{ cm}^2/\text{V-sec}$. Time-of-flight measurements report such transient mobilities in materials whose steady-state thermally activated mobilities suggest small-polarons.

Polarons' Seebeck coefficients

The Seebeck coefficient S measures the open circuit e.m.f. $\Delta\phi$ developed across a material in response to the application of the temperature difference ΔT : $S \equiv \Delta\phi/\Delta T$. In physical terms the Seebeck coefficient S is the entropy transported with a carrier divided by its charge q . A charge carrier's Seebeck coefficient is related to its Peltier heat, $\Pi = qTS$, the heat transported with a charge carrier.

Analysis of Seebeck coefficient measurements aids understanding charge transport generally and polaron transport, in particular. Combined measurements of the Seebeck coefficient and the dc conductivity distinguish between small-polaron hopping and other models of hopping transport. Large and unusual polaron-based Seebeck coefficients have been exploited to produce novel thermoelectric devices.

There are several different contributions to the Seebeck coefficient. The primary contribution is often the change of the entropy-of-mixing upon adding a carrier of energy E and charge q to a system of chemical potential μ : $\langle E - \mu \rangle_{\sigma}/qT$, where the brackets indicate an average of states' energies weighted by their contributions to the electrical conductivity σ .

It is sometimes useful to consider the entropy-of-mixing contributions to Seebeck coefficients as functions of c , the ratio of the number of charge carriers to the number of a material's equivalent structural units. When carriers exist in an energy band that is narrower than kT the Seebeck coefficient becomes temperature independent equal to $(k/e)\ln[(2-c)/c]$ for fermions that can doubly occupy a state, $(k/e)\ln[2(1-c)/c]$ for fermions that can singly occupy a state but with a two-fold spin degeneracy, and $(k/2e)\ln[(2-c)/c]$ for carriers that pair as $c/2$ singlet bipolarons which can only singly occupy a state.

The magnitude of the entropy-of-mixing contribution to a semiconductor's Seebeck coefficient is usually much greater than $(k/e) = 86 \mu\text{V/K}$. Nonetheless, the third law of thermodynamics requires that the entropy and hence the Seebeck coefficient vanish at absolute zero. The magnitude of a semiconductor's Seebeck coefficient drops precipitously to near zero when the ratio of kT to the carrier bandwidth becomes very small (Emin, 2016). Thus, the temperature of this dramatic fall indicates whether the carrier's energy band is consistent with conventional charge carriers, several eV, or with polarons, less than the phonon energy, 0.03–0.1 eV.

The magnetic moment of a charge carrier is found by measuring the magnetic-field dependence of the Seebeck coefficient. In particular, the magnetic field H breaks the two-fold spin degeneracy of singly occupied states. The Seebeck coefficient's spin degeneracy factor then becomes $(k/e)\{\ln[2\cosh(\mu_B H/kT)] - (\mu_B H/kT)\tanh(\mu_B H/kT)\}$, where μ_B represents the carrier's magnetic moment. A significant H -dependent fall of this factor from $(k/e)\ln(2)$ to zero is expected below 10 K at fields exceeding 10 T. The absence of this Seebeck-coefficient magnetic-field dependence implies that charge carriers have no net magnetic moment since they have paired into singlet bipolarons.

The conductivity activation energy for Arrhenius small-polaron hopping between equivalent states is the sum of that for carrier generation and that of the mobility: $(E_S - \mu) + E_A$, while the characteristic energy of the Seebeck coefficient is simply $E_S - \mu$. Therefore, the difference of the characteristic energies obtained from dc conductivity and Seebeck coefficient measurements is just that of the mobility E_A . Observing a significant value of E_A is often taken as evidence of small-polaron hopping.

As in a semiconductor's band tail, phonon-assisted hopping can be envisioned as occurring between severely localized states that are strongly coupled to phonons and weakly-localized states that are weakly coupled to phonons. The transported vibrational energy from a hop between states i and j then contributes to the Seebeck coefficient:

$$S_{ij} = \frac{E_i \left(\frac{\Gamma_j}{\Gamma_i + \Gamma_j} \right) + E_j \left(\frac{\Gamma_i}{\Gamma_i + \Gamma_j} \right) - \mu}{qT}, \quad (11)$$

where Γ_i and Γ_j denotes the electron-phonon coupling of these states. When one initial state is much more strongly coupled to phonons than the other state, $\Gamma_s \gg \Gamma_w$, the Seebeck coefficient between them is always related to the more weakly coupled state, $(E_w - \mu)/qT$. Thus, the Seebeck energy for thermally exciting carriers from deep within a bandgap to near a band- or mobility-edge is comparable to that of the conductivity. By contrast, the Seebeck energy for small-polaron hopping is significantly smaller than the conductivity activation energy.

Self-trapped electronic carriers adjust to displacements of surrounding atoms from their equilibrium positions. These adjustments generally reduce the frequencies of these atoms' vibrations. The associated carrier-induced increase of the net vibrational entropy contributes to the Seebeck coefficient. With increasing temperature this contribution to the Seebeck coefficient rises from zero at absolute zero to its high-temperature limit: $(k/q)\Sigma_i (-\Delta\omega_i/\omega_i)$ for moderate frequency shifts, $(-\Delta\omega_i/\omega_i) \ll 1$, where $\Delta\omega_i$ denotes the carrier-induced change of the frequency of the i -th vibration mode ω_i .

By itself, carrier-induced softening also fosters vibrational energy being transported with a phonon-assisted hop. For example, the contribution to the Seebeck coefficient from a high-temperature Arrhenius small-polaron hop between equivalent states is $(1/qT)\Sigma_i (-\Delta\omega_i/\omega_i)(E_{p,i}/2)$, where $E_{p,i}$ denotes the i -th vibrational mode's contribution to the small-polaron's binding energy. This contribution rises with decreasing temperature to a peak at a fraction of the characteristic phonon temperature and then falls to zero at absolute zero. The large Seebeck coefficients, >200 $\mu\text{V/K}$ above 300 K, seen in boron carbides despite their very high bipolaron densities are attributed to bipolaron-induced vibrational softening (Emin, 2006).

Carrier-induced magnetic changes also manifest themselves in the Seebeck coefficient. In particular, the previously-suggested model of large-bipolaron formation within the CuO_2 planes of doped- La_2CuO_4 has each large-bipolaron removing a spin-1/2 from each of its four adjacent Cu cations. Distinctively, this effect lowers the Seebeck coefficient of such a large bipolaron by eliminating the entropy associated with these spins' orientations. In the high-temperature paramagnetic region the spin-related reduction of these large-bipolarons' Seebeck coefficients reaches $-(k/e)[4\ln(2)]$.

Polarons' Hall mobilities

A current produced by an electric field tends to be deflected by the application of a transverse magnetic field. This deflection angle, the Hall angle, divided by the magnetic field's strength defines the Hall mobility μ_H . By contrast, a charge carrier's drift velocity divided by the electric field driving its flow defines the usual mobility μ . Since μ_H and μ measure different phenomena, they generally differ from one another. Nonetheless, a simple treatment of coherent transport in an energy band that is much wider than the thermal energy kT yields $\mu_H = \mu$. However, significant differences between μ_H and μ emerge for coherent charge transport in energy bands that are narrower than the thermal energy kT . The dissimilarity between these two mobilities becomes profound for charge carriers that move incoherently by thermally assisted hopping. Then μ_H and μ differ from one another in magnitude, temperature dependence and often even in sign. These distinctive features facilitate identifying charge carriers as small polarons.

The Hall Effect centers on the deflection of charge carriers in a magnetic field. As such, the small-polaron Hall Effect requires considering at least a planar array of sites. Models for studying the Hall Effect envision a magnetic field applied perpendicular to a planar lattice comprising tiles of equilateral triangles and a planar lattice comprising square tiles.

A magnetic field alters transport among the sites of a planar lattice's primary structural unit, equilateral triangle or square. The magnetic field contributes a site-dependent phase factor to each site's electronic wavefunction. Electronic transfer energies therefore garner magnetic phase factors that depend on the linked sites. From this starting point two complementary approaches have been employed to calculate the small-polaron Hall Effect in the high-temperature Arrhenius regime.

The non-adiabatic limit presumes very small electronic inter-site transfer energies. Then an electronic carrier rarely moves between sites in response to opportunities presented by atoms' motions. Concomitantly, this approach's basis states are each localized on a site. The magnetic field's influence then results from interference between different transfer processes. For example, interference on a triangle occurs between a direct inter-site transfer and an indirect transfer through the third site. This interference depends on the magnetic flux through a lattice's primary structural unit.

The adiabatic limit presumes that an electronic carrier always responds to atomic movements by moving to the lowest-energy site of its molecular orbital. This behavior can be portrayed with a generalization of the one-dimensional configuration-coordinate diagram of Fig. 4. In particular, an electronic charge carrier moving among the three sites of an equilateral triangle corresponds to a fictitious particle moving among three mutually adjacent quasi-harmonic potential wells of a two-dimensional adiabatic potential surface. The magnetic field converts the real wavefunction describing the electronic carrier's non-degenerate molecular orbital into a complex wavefunction. As a result, terms proportional to atomic momenta of the adiabatic Hamiltonian survive to act like a fictitious vector potential. The magnetic field corresponding to this fictitious vector potential is proportional to the real applied magnetic field. This magnetic field affects the motion of the adiabatic potential's fictitious particle. Moreover, the fictitious magnetic field is strongest along the ridges separating adjacent quasi-harmonic potential wells. The magnetic field thereby shifts

fictitious-particle trajectories corresponding to shifting the final site of an electronic carrier's hop. Analysis of these trajectories yields the adiabatic small-polaron Hall Effect.

The Hall mobility is ideally intrinsic, unaffected by trapping, since the Lorentz force only deflects a moving charge carrier. The magnitude of the small-polaron Hall mobility is at most comparable to $1 \text{ cm}^2/\text{V}\cdot\text{s}$. Most importantly, the activation energy of the small-polaron Hall mobility in its high-temperature Arrhenius regime is always less than that of the conventional mobility. In particular, although the ratio of these two activation energies depends on the details of the model, the activation energy of μ_H for small-polaron hopping is often about one-third that of μ . Furthermore, the Hall mobility activation energy even can be small enough that the temperature dependence of μ_H is dominated by that of its pre-exponential factor. In these instances, the Hall mobility will decrease with increasing temperature.

The sign of the Hall coefficient in wide-band conventional semiconductors is (1) negative for electrons in states with positive effective mass near conduction-band minima and (2) positive for vacant electronic states with negative effective mass near valence-band maxima. This simple situation does not always apply for energy bands which are narrower than the thermal energy kT . Moreover, Hall-Effect sign anomalies, opposite those for charge carriers in conventional semiconductors, are common for small-polaron hopping.

The sign of the Hall coefficient for hopping conduction is given by

$$\text{sgn}(R_H) = \text{sgn} \left[(-q)(\delta)^{n+1} \prod_{i=1}^n t_{i,i+1} \right], \quad (12)$$

where q denotes the bona-fide carrier's charge (negative for electrons). In addition, δ indicates the filling of the states between which carriers hop ($\delta = -1$ for nearly empty states and $\delta = 1$ for nearly filled states). The final factor in the above equation is the product of electronic transfer energies $t_{i,i+1}$ integrals around a closed loop of n elements.

The sign of the Hall coefficient is conventional when the charge carriers are electrons ($q < 0$) moving among sites for symmetric structures in which n is even. Then the Hall coefficient sign is just that of δ : negative for nearly empty states ($\delta = -1$) and positive for nearly filled states ($\delta = 1$). Similarly, the sign of the entropy-of-mixing contribution to the Seebeck coefficient, proportional to $\ln[c/2(1-c)]$ or $\ln[c/(1-c)]$, is negative for a nearly empty narrow band of electrons, $c < 1/2$, and positive for a nearly full narrow electron band, $c > 2/3$.

By contrast, the sign of the Hall coefficient is often anomalous for electrons moving among sites for which n is odd, as frequently occurs for non-crystalline structures. Then the sign of the Hall coefficient is just that for the product of electronic transfer energies, independent of state filling. The sign of this product only depends on the symmetry of the orbitals between which electrons transfer.

The product of n -transfer energies between node-less electronic states (e.g., bonding, lone-pair or ground-state impurity orbitals) is simply $(-1)^n$ because of the negative potential in orbitals' overlap regions. The sign of the Hall coefficient is then negative when n is odd, even while the sign of the Seebeck coefficient is positive for transport among nearly filled bonding, lone-pair or impurity-state orbitals.

Furthermore, the product of n -transfer energies between anti-symmetric (e.g., anti-bonding) orbitals is always positive. Thus, the sign of the Hall coefficient is positive for hopping in structures dominated by odd membered loops of antibonding orbitals. This result is opposite to the negative Hall coefficient for conventional transport involving transport among anti-bonding orbitals of a covalent semiconductor's conduction band.

Very low, $< 1 \text{ cm}^2/\text{V}\cdot\text{s}$, thermally activated Hall mobilities have been reported in many non-crystalline solids. Their Hall mobility activation energies are generally considerably smaller than the mobility activation energies inferred from comparison of the temperature dependences of these materials' dc conductivities and Seebeck coefficients. Hall-Effect sign anomalies are also widely reported in disordered structures that manifest hopping transport. Most strikingly, positive Hall coefficients are reported when doping introduces low-mobility hopping electrons to amorphous elemental Si and As. Negative Hall coefficients with Arrhenius Hall mobilities are also reported when dopants remove electrons from amorphous elemental Si and Ge. Unlike their crystalline counterparts, these elemental covalent semiconductors are thought to contain significant numbers of odd-membered rings. Negative Hall coefficients and positive Seebeck coefficients are widely reported for chalcogenide glasses where transport is thought to be between lone-pair orbitals on chalcogen atoms. Small-polaron-like transport between dopant-related states in heavily doped semiconductors also display negative Hall coefficients with positive Seebeck coefficients.

Polaron absorption

Large- and small-polarons generate broad absorption bands. Features of their absorptions distinguish between them.

A large-polaron's principal absorption arises from photo-exciting its self-trapped electronic carrier into the energy band which is its genesis. The potential well binding a large-polaron's electronic carrier is approximated as that formed with surrounding atoms fixed at their carrier-induced equilibrium positions. For a Coulomb-like self-trapping potential well, the threshold for photo-ionizing its electronic carrier occurs when the photon energy $\hbar\Omega$ exceeds three times the large-polaron binding energy $3E_p$. Since $E_p \gg \hbar\omega$ for a strong-coupling large-polaron, the threshold for its main absorption lies above the characteristic phonon energy $\hbar\omega$. Above this threshold the absorption increases as it mirrors the rise of the energy band's density-of-states beyond its edge. This large-polaron's absorption band subsequently declines gradually as the wave-lengths of the energy band's Bloch states fall below the self-trapped electronic carrier's spatial extent. Thus, a large-polaron primary absorption band tends to rise more sharply with

increasing Ω below its peak than it declines subsequently. In addition, subsidiary narrow absorption bands can emerge from exciting self-trapped electronic carriers into their intra-well excited states.

Coherently moving charge carriers exhibit a Drude-type absorption corresponding to the real part of the frequency-dependent conductivity, $\text{Re}[\sigma(\Omega)] = \sigma(0)/[1 + (\Omega\tau)^2]$, where τ denotes the carrier's scattering time. Large polarons are extremely slow-moving, heavy-massed and weakly scattered compared with conventional electronic charge carriers. In particular, the scattering time associated with a large-polaron's scattering by acoustic phonons is so long that the large-polaron Drude absorption is confined to well below the characteristic phonon energy $\hbar\omega$. Moreover, this scattering time increases as the temperature is reduced. Therefore, the pseudo-gap between a large-polaron's low-frequency Drude absorption, $\Omega < \omega$, and the threshold of its high-frequency broad absorption band, $\Omega > \omega$, widens as the temperature is lowered. This signature behavior is unlike that of conventional electronic carriers whose Drude absorption simply falls monotonically with increasing frequency up to very high frequencies, e.g., $\Omega \approx 10^{15}$ Hz.

A small-polaron absorption is a photo-induced transition between severely localized electronic states. It elevates a small-polaron's self-trapped electron from its adiabatic ground-state into a severely localized state centered on a nearby unoccupied site. With a short-range electron-phonon interaction the absorption's peak is at twice the small-polaron binding energy. This absorption is broadened as vibrations of atoms surrounding its initial and final sites spread their electronic energies. With increasing temperature this broadening increases from that due to atoms' zero-point vibrations to that due to their thermal vibrations. The asymmetry of a small-polaron absorption band is opposite that of a large-polaron's primary high-frequency absorption band. In particular, the small-polaron absorption rises more slowly with increasing Ω below its peak than it falls above its peak.

Interactions between polarons

Transient absorptions, recombination and possible luminescence are governed by the interactions between injected oppositely-charged carriers that form polarons. Polarons are indicated by their mobilities being well below the minimum for non-polaron carriers, $q\hbar/m_c kT$, about $300 \text{ cm}^2/\text{V}\cdot\text{s}$ at room temperature. Since polarons are slow moving, the energy of their mutual Coulomb interaction is reduced by their material's static dielectric constant ϵ_0 . Well-separated polarons also each lower their energies by their polaron binding. However, as oppositely charged polarons approach close enough to one another the pair increasingly presents itself to surrounding atoms and ions as being charge neutral. As a result, their net polaron binding energy is reduced, increasing the energy of a pair of oppositely charged polarons. In other words, there is a short-range repulsion between oppositely charged polarons. Finally, when electron and hole polarons share a common site, they simply become a self-trapped exciton. Consistent with its charge neutrality, an exciton has a much smaller energy reduction from displacement of surrounding atoms than do a separated electron and hole. These features are illustrated in Fig. 7, where, the energy of oppositely charged polarons is plotted against their separation s . The short-range repulsion between oppositely charged polarons is most severe in materials with especially displaceable ions, solids with exceptionally large static dielectric constants. The suppression of recombination in such materials (e.g., perovskites) fosters their functioning as especially efficient solar cells (Emin, 2018).

Repulsive interactions occur between polarons of like-charge as their self-trapped electronic carriers compete to displace intervening atoms. Self-trapping then becomes untenable at sufficiently large charge-carrier densities. This effect is the basis of a mechanism to switch a low-conductivity small-polaron semiconductor into a higher conductivity state. Specifically, current flow drives conventional electronic charge carriers from conducting leads into a semiconductor in which they form small-polarons. Small polarons diffuse much slower than conventional carriers. As a result, increasing current flow causes small polarons to progressively accumulate in the semiconductor near its interfaces with its conducting contacts. A high enough current will augment this interfacial

Fig. 7 The energy of a pair of oppositely charged polarons $E_{p,pair}$ in units of the net energy of the pair of well-separated polarons, is plotted against their mutual separation s in units of the sum of the radii of their self-trapped electronic carriers, R_{p+} and R_{p-} . The energy reduction from relaxation of well-separated charged polarons, $s \rightarrow \infty$, is much larger than that for a self-trapped exciton, $s \rightarrow 0$. The repulsive portion of the curve is shown in red.

Fig. 8 The current I is plotted versus the voltage V for a threshold switch. The low-conductivity state is shown in blue and the high-conductivity state is depicted in red. The high-conductivity state is maintained provided I is kept above its threshold value.

concentration of small polarons enough to destabilize them, converting them into conventional carriers. The large interfacial concentration of small polarons thereby propagates into the semiconductor. If the propagated small-polaron concentration remains sufficiently large it too will be destabilized. The avalanche of converting small-polarons into conventional carriers will continue until the excessive small-polaron concentration is relieved (e.g., by recombination with oppositely charged carriers entering from the opposing contact). The resistance of the switched semiconductor is then primarily that of the residual region whose charge carriers remain as small polarons. The hallmark of such switching is that the resistance in the high-conductivity state is independent of the semiconductor's length since it mainly depends on the length of the residual region. As illustrated in Fig. 8, the higher conductivity state persists as long as the current is maintained above the threshold needed to initiate switching from the low-conductivity state. Furthermore, threshold switches can be converted into memory switches if their relatively large current flows induce ("burns in") structural changes into the semiconductor. Such switching has been reported for about a century in materials (e.g., chalcogenide glasses) whose very low thermally activated mobilities suggest that their charge carriers are small-polarons.

A large singlet bipolaron has two self-trapped electronic carriers with opposing spin alignments sharing a common multi-site ground-state orbital. The Pauli principle requires that further electronic carriers added at the bipolaron's location be placed in orbitals of higher energy. This promotion energy destabilizes such multi-carrier entities with respect to separating into bipolarons and polarons. Thus, singlet bipolarons are the only multi-carrier polarons. In other words, there is a hard-core short-range repulsion between singlet bipolarons. Bipolarons also experience a mutual Coulomb repulsion. Since a bipolaron's motion is very slow, governed by associated atoms' movements, this long-range repulsion is reduced by its material's static dielectric constant, ϵ_0 . This suppression is severe for large singlet bipolarons since, as noted earlier, their stability with respect to both (1) separating into two large polarons and (2) collapsing into a small bipolaron requires a material with exceptionally displaceable ions, $\epsilon_0 > 2\epsilon_\infty \gg 1$. The polarization of a large bipolaron's self-trapped electronic carriers in response to related atoms' vibrations reduces their energies. This softening of atoms' vibrations increases with the density of large-bipolarons. In other words, there is a phonon-mediated intermediate-range attraction between large bipolarons. The combination of large-bipolarons' mutual short-range repulsion, suppressed Coulomb repulsion and intermediate-range attraction fosters a gas of large bipolarons condensing into a large-bipolaron liquid. In addition, the liquid's density is limited in order to avoid destabilizing its large bipolarons.

Superconductivity of a large-bipolaron liquid

Conventional superconductivity occurs in elemental metals such as Al, Hg, Pb, La, Nb, Sn and Ta with transition temperatures below 10 K. Unconventional superconductivity occurs in doped transition-metal-oxide insulators with especially displaceable ions, as indicated by their exceptionally large values of $\epsilon_0/\epsilon_\infty$. The ferroelectric insulator SrTiO_3 is a perovskite ferroelectric whose structure can be viewed as comprising alternating planar TiO_2 and SrO layers. It displays superconductivity below 1 K when charge carriers are introduced by Nb substitutions or oxygen vacancies. Much higher superconducting transition temperatures are found upon doping cuprate insulators which have more complicated perovskite-based structures. For example, La_2CuO_4 is comprised of CuO_2 layers alternating with two LaO layers. Holes are introduced in the CuO_2 layers when divalent cations such as Sr^{2+} or Ba^{2+} cations are substituted for La^{3+} . Cuprate superconductors have superconducting transition temperatures, between about 30 K and 130 K.

The charge carriers in the normal states of conventional superconductors are quasi-free electrons. By contrast, the charge-carriers in transition-metal oxides are widely viewed as some type of polaron. In particular, polarons related to the relatively narrow bands associated with motion between transition-metal ions usually are small. Polarons associated with the relatively wide oxygen-based electronic bands are typically large. Moreover, singlet large-bipolaron formation is strongly promoted when carriers are confined to a plane embedded within a medium for which $\epsilon_0/\epsilon_\infty \gg 1$.

Conventional superconductivity's genesis is a phonon-mediated attraction between quasi-free electrons that induces their condensing into singlet pairs. These Cooper pairs overlap very strongly with one another to produce a quantum liquid

whose ground state has an energy gap in its excitation spectrum. An unconventional model of superconductivity envisions the phonon-mediated intermediate-range attraction between large bipolarons driving their condensation into a liquid of non-overlapping charged bosons. The ground state of this liquid remains fluid, rather than condensing into a solid, if its large bipolarons do not order in a manner commensurate with its solid's underlying lattice. Large-bipolaron superconductivity is then akin to the superfluidity of a liquid of neutral mobile bosons, liquid ^4He , but with mobile bosons of charge $2e$, a large-bipolaron liquid. As such, the liquid's long-wavelength excitations are just the large-bipolarons' plasma oscillations. These excitations' characteristic energy is $\hbar\Omega_p \equiv \hbar[4\pi(2e)^2 n_{\text{lb}}/m_{\text{lb}}\epsilon_0]^{1/2}$, where n_{lb} and m_{lb} respectively denote the large-bipolaron density and effective mass. The very large values of m_{lb} and ϵ_0 , which characterize large bipolarons and their formation, limit $\hbar\Omega_p$ to less than that of related phonons $\hbar\omega$. The liquid's Bose condensation and the onset of large-bipolaron superconductivity occurs when kT falls below $\hbar\Omega_p$. The liquid's collective ground state is characterized by the synchronous zero-point vibrations of the atoms whose displaced-equilibrium positions generate the potential wells that self-trap the singlet pairs of its large bipolarons.

Superconductors based on doped ionic insulators display properties consistent with two-fluid large-bipolaron superconductivity. The scattering of channeled ions and the positron annihilation rate progressively fall as the homogeneous synchronous vibrating condensate grows upon lowering the temperature below the superconducting transition temperature.

Distinctive properties reported for superconductors based on doped ionic insulators are consistent with those of large bipolarons. The very high superconducting transition temperatures in cuprates may simply result from their large values of ϵ_0 (≥ 50) being considerably smaller than those of doped-SrTiO₃, a bona-fide ferroelectric, with $\epsilon_0 \approx 20,000$ near its superconducting temperature, about 1 K.

As illustrated in Fig. 9, large-bipolarons' superconductivity requires their density to be (1) large enough to avoid their being bound to dopants, (2) small enough to preclude their destabilization, and (3) incommensurate with their ground-state's global solidification. For example, superconductivity in tetragonal $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ only exists over a restricted doping range and disappears at an intermediate doping level that is commensurate with bipolarons' global solidification: a bipolaron centered on every fourth CuO_2 unit in the x and y directions of its planar square lattice, $2/(4 \times 4) = 1/8$.

The pseudo-gaps observed in cuprate superconductors' absorption spectra resemble the temperature-dependent gap between a large-(bi)polaron's low-frequency, $< \hbar\omega$, Drude absorption and the broad high-frequency, $> \hbar\omega$, absorptions generated by exciting its self-trapped electronic carriers. Normal-state carrier mobilities in cuprates, about $1 \text{ cm}^2/\text{V-s}$, are much less than the minimum for coherent transport, eh/kTm_c , if the carrier mass m_c is comparable to that of an electron. However, measured mobilities are compatible with large-(bi)polarons' huge effective masses.

As illustrated in Fig. 3, the core of a large-bipolaron in single-cuprate-layer superconductors is envisioned as two electrons being removed from the four O^{2-} anions circumscribed by four spin-1/2 Cu^{2+} cations residing at the corners of a CuO_2 planar square unit (Emin, 2017). Self-trapping occurs as the oxygen anions relax inward and the copper cations relax outward. Concomitantly, four electrons are transferred from the oxygen anions to the copper cations thereby converting them to spin-less Cu^{1+} cations. The carrier-induced loss of magnetism and its spin entropy generates a negative contribution to the large-bipolaron-hole's Seebeck coefficient. It falls toward $-(k/2e)[4\ln(2)]$ with rising temperature. The superconducting state's synchronous lowest-frequency and largest-amplitude radial zero-point optic-mode vibrations of carrier-induced displaced oxygen and copper atoms have d -symmetry. The adiabatic principle insures that the symmetries of these atoms' equilibrium and zero-point vibratory displacements will be reflected in their electronic states.

Fig. 9 The superconducting transition temperature of tetragonal $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ is plotted versus x , the idealized concentration of doping-induced holes. Superconductivity exists between limiting dopant concentrations. Distinctively, as observed, superconductivity also vanishes at the intermediate hole concentration $x = 1/8$. This concentration corresponds to doping-induced holes ordering as bipolarons commensurate with the basal plane's CuO_2 square lattice at $x = 2/(4 \times 4) = 1/8$.

Conclusion

An electronic charge carrier is self-trapped when it is bound within the potential well generated by displacing atoms to new equilibrium positions. Self-trapping requires that the binding energy of the self-trapped carrier exceed $h\nu$, where ν denotes the characteristic frequency of associated atoms' vibrations. The electronic carrier then circulates within the potential well that binds it before the associated atoms move appreciably. Relaxation of self-trapped electronic carriers to these atoms' vibrations lowers their frequencies. A strong-coupling polaron refers to the composite quasiparticle comprising the self-trapped electronic carrier taken together with the alterations it induces in related-atoms' equilibrium positions and vibrations.

Polaron formation is driven by a charge carrier's short-range and long-range electron-phonon interactions. These interactions result from the respective dependences of an electronic charge carrier's energy on the locations of the atoms it contacts and on displacements of distant ions. A macroscopic measure of the displaceability of these ions is the difference between the reciprocals of a material's high-frequency and static dielectric constants: $\epsilon_\infty^{-1} - \epsilon_0^{-1}$. For ionic and polar media $\epsilon_0 \gg \epsilon_\infty$, but for covalent media $\epsilon_0 \approx \epsilon_\infty \gg 1$. Carrier-induced changes in the separations between dissimilar atoms shift charge between them.

The adiabatic limit, $\nu \rightarrow 0$, presumes that electronic charge carriers always adjust to the motions of media's relatively massive and slow moving atoms. The adiabatic potential energy is the sum of the potential energy arising from atomic displacements plus the electronic carrier as a function of atoms' positions. Adoption of a scaling argument enable the adiabatic potential to be readily studied as a function of an electronic carrier's spatial extent, its radius. A minimum of the adiabatic potential with respect to a carrier's radius indicates its being self-trapped. There are two distinct types self-trapped state. A large-polaron minimum, corresponding to a self-trapped electronic carrier extending over multiple sites, forms when long-range electron-phonon interactions predominate. A small-polaron minimum, characterized by the self-trapped electronic carrier collapsing to the most severely localized state consistent with condensed-matter's atomicity, forms when the short-range electron-phonon interaction predominates.

Self-trapped charge carriers move very slowly since their movement is contingent on atomic movements. Strong-coupling large polarons move coherently albeit with huge effective masses. As such, the minimum mobility permitted for coherently moving charge carriers (eh/kTm_c , where m_c denotes a charge-carrier's effective mass) is much lower for large polarons than for conventional electronic charge carriers. Nonetheless, large-polaron mobilities are higher than might be expected because such heavy-massed quasi-particles tend to be difficult to scatter. Large-polaron mobilities are frequently about 1–10 cm²/Vs at room temperature.

Small polarons generally move incoherently by thermally assisted hopping. Small-polaron mobilities are Arrhenius at high temperatures and become non-Arrhenius as the temperature is lowered below about $h\nu/3k$. In particular, the high-temperature adiabatic small-polaron mobility is $(ea^2\nu/kT)\exp(-E_A/kT)$, where a denotes the jump distance and $E_A > h\nu$. By itself, the increase of E_A with increasing jump distance favors short hops over long hops. The slowness of transfers of vibrational energy between the atoms directly related to a hop and the remainder of the medium causes hopping to occur in flurries separated by quiescent periods. An injected charge carrier's relaxation as it forms a small polaron generates a region of enhanced vibrational agitation. Its transient hopping is thereby enhanced until its full equilibration is achieved.

The Seebeck coefficient, the entropy transported with a carrier divided by its charge, displays features which distinguish polarons from conventional charge carriers. Often the change of the entropy-of-mixing generated by adding a charge carrier provides the dominant contribution to the Seebeck coefficient. Then the Seebeck coefficient just depends on the carrier concentration. By contrast, the dc conductivity also depends on charge-carriers' mobility. Taken in tandem, measurements of the Seebeck coefficient and the dc conductivity permit determination of whether the carrier mobility manifest the Arrhenius high-temperature behavior characteristic of small-polaron hopping. The Seebeck coefficients of large (bi)polarons are also distinctive in that they have contributions from carrier-induced reductions of related atoms' vibration frequencies.

Distinctively, the Hall mobility, the mobility determined from a Hall-Effect measurement, for small-polaron hopping generally rises more slowly with increasing temperature than does the mobility which enters into the dc conductivity. Moreover, the sign of the small-polaron Hall Effect is often opposite to were the charge carriers conventional. These anomalous situations occur in many amorphous semiconductors, for semiconductors' impurity conduction, and for some crystalline structures.

Since large polarons are massive and relatively difficult to scatter, the declines of the real part of their conductivities with increasing applied frequency primarily occur well below those of atomic vibrations, 10¹³ Hz, rather than at the relative high frequencies, 10¹⁵ Hz, characterizing conventional electronic charge carriers. In addition, the large-polaron frequency-dependent conductivity associated with exciting its self-trapped electron carrier occurs above atomic vibration frequencies. Thus, unlike a conventional electronic carrier, a large-polaron's absorption spectrum has a low-energy gap which widens with decreasing temperature. Small polarons' absorption spectra are also qualitatively distinct from those of conventional electronic charge carriers. The photon-assisted inter-site transfer of a small-polaron generates a broad absorption band which peaks at an energy of about four times the hopping activation energy.

Distinctive features of (bi)polarons' mutual interactions support some device applications. In particular, as oppositely charged polarons approach one another their net interaction with distant ions progressively diminishes. The net polaron-formation energy is thereby reduced. In other words, there is a short-range repulsion between oppositely charged polarons (Emin, 2018). By suppressing recombination of oppositely charged large polarons in ionic solids this effect fosters their solar cell efficiency. This effect may account for the high efficiencies of perovskite solar cells whose (1) very large values of $\epsilon_0/\epsilon_\infty$, (2) moderate carrier mobilities (i.e., about 1 cm²/V-s at 300 K), and (3) distinctive absorption spectra suggest large-polaron formation. This effect would

also increase the feasibility of high-efficiency, long-lived, high-power, beta-voltaic devices (Emin, 2019). These devices are stacks of p-n junctions of doped icosahedral boride semiconductors in which a reliable, high intensity beta-particle flux from a radio-isotope (e.g., ^{90}Sr) replaces a solar-cell's intermittent moderate-intensity solar flux.

The density of stable polarons is limited by their competition to displace surrounding atoms. Thus, introducing ever higher concentrations of polarons into a semiconductor ultimately destabilizes them with respect to their forming conventional high-mobility electronic charge carriers. Thus, driving a large enough current through a semiconductor whose equilibrated carriers are small polarons cause it to switch into a low resistance state. This low-resistance state is maintained by keeping the current above the threshold value at which switching is initiated.

Charge carriers can pair as singlet large-bipolarons in materials with exceptionally displaceable ions as indicated by $\epsilon_0/\epsilon_\infty \gg 1$. The phonon-mediated attraction between large bipolarons, generated by their self-trapped electrons' collective response to atoms' vibrations, fosters their condensing into a liquid. Superconductivity is associated with the Bose condensation of this large-bipolaron liquid. Distinctive features distinguish this superconductivity from metals' conventional superconductivity. In particular, (1) large bipolarons and their liquid only exist for moderate carrier concentrations, (2) the normal-state large-bipolaron mobility is much less than that permitted for conventional electronic charge carriers, and (3) large-bipolarons' normal-state absorption spectra have low-energy gaps that widen with decreasing temperature.

Electronic charge carriers that self-trap, thereby forming strong-coupling (bi)polarons, display transport and optical properties which distinguish them from conventional carriers. Large polarons display exceptionally low mobilities that decrease with increasing temperature. A large-polaron's absorption spectra consist of a broad high-frequency band that is separated by a pseudo energy gap from an extremely narrow low-frequency Drude-type absorption. Small polarons manifest thermally-assisted mobilities which are usually very much lower than even large-polaron mobilities. Distinctively, small-polaron mobilities become Arrhenius at high temperatures. A small-polaron's Hall-Effect mobility increases with rising temperature more gently than that of the mobility which enters into the dc conductivity. In many materials a magnetic field deflects a small polaron in the opposite direction as it would deflect a free carrier of the same charge. A broad small-polaron absorption band is associated with photon-assisted hopping. Oppositely charged polarons experience mutual short-range repulsion which impede their recombination. Polarons of like charge can combine to form singlet bipolarons in materials with exceptionally displaceable ions. Large bipolarons may even condense into a liquid which undergoes a Bose condensation to yield unconventional superconductivity. Reports of most of these extraordinary effects already exist. Observations of the unusual properties which identify strong-coupling polarons may become more common as increasingly complex semiconductors are investigated.

Abstract

This chapter explores extremely narrow gap semiconductors and semimetals resulting from microscopic interactions between itinerant electrons. It focuses on spin-density waves, which emerge from Coulomb interactions, transforming metals into antiferromagnetic systems. The chapter discusses their perturbations of electronic bands, thermodynamic coupling, and stability under magnetic fields. It examines the instability at the Fermi surface, static and dynamic properties, and transitions between field-induced phases. Potential applications to other density wave states are briefly discussed. This review provides a concise understanding of spin-density waves' phenomena and their significance in semiconductors.

Key points

- Focus on spin-density waves as a consequence of Coulomb interactions between electrons, leading to antiferromagnetic behavior in a metal.
- Consider spin-density waves as perturbations of electronic bands of quasiparticles in a metal, with smaller gaps and metallic carriers surviving in some cases.
- Explore the mapping of antiferromagnetism onto the case of a Heisenberg antiferromagnet, with smaller moments and spatial periodicities.
- Investigate the thermodynamic coupling between spin-density waves and charge degrees of freedom, leading to phase excitations and changes in spin orientation.
- Analyze the instability at the Fermi surface responsible for spin-density wave formation and discuss their static and dynamic properties.
- Examine field-induced spin-density waves and the role of orbital contributions in stabilizing ground states under a strong magnetic field.
- Explore transitions between different field-induced spin-density wave phases and their connection to the bulk quantum Hall effect.
- Refer to the potential application of spin-density wave formalisms to other density wave states involving pseudospins, such as quadrupole-density waves, valley-density waves, or chirality-density waves.

Nomenclature

t_b'	Transfer integral along b (second nearest neighbor) [J, eV]
$\epsilon_{\perp}$	Electronic dispersion orthogonal to x [J, eV]
2Δ	Gap energy [J, eV]
A or B	Arbitrary integers [dimensionless]
a or b	Lattice constant along x or y [m]
A	Vector potential [Tm]
B or B	Magnetic flux density (magnetic field) [T]
B_{eff}	Heisenberg molecular field [T]

D	Anisotropy energy [J, eV]
E	Electric field [Vm^{-1}]
e	Electron charge [C]
g	Electronic g -factor [dimensionless]
H	Heisenberg spin Hamiltonian [J, eV]
$H_{\perp}$	Anisotropy Hamiltonian [J, eV]
h	Planck constant [Js]
$\hbar$	Planck constant divided by 2π [Js]
i	Square root of -1 [dimensionless]
J	Heisenberg interaction [J, eV]
j_{SDW}	Current of collective mode [Cs^{-1}]
k	Electronic wave vector [m^{-1}]
k	Wave number [m^{-1}]
k_{F}	Fermi wave vector [m^{-1}]
k_x, k_y or k_z	Electronic wave vector along x , y or z [m^{-1}]
l	Landau level index [dimensionless]
m or μ	Moment of spin [Am^2 or units of μ_{B}]
m	Effective mass [kg]
n	Carrier density (3D) [m^{-3}]
N	Number of electrons per unit cell [dimensionless]
p or q	Indices of spin [dimensionless]
Q	Quasiparticle excitation wave vector [m^{-1}]
Q_0 or Q_0	Optimum nesting vector [m^{-1}]
S or S	Spin per unit cell [dimensionless]
T	Temperature [K]
t	Time [s]
t_b	Transfer integral along b (nearest neighbor) [J, eV]
T_{SDW}	Transition temperature [K]
U	Coulomb potential [J, eV]
V	Volume of unit cell [m^3]
v_{F} or v_{F}	Quasiparticle group velocity at Fermi surface [ms^{-1}]
W	Electronic bandwidth [J, eV]
x	Spatial dimension along x [m]
ε	Electronic dispersion [J, eV]
ε_{F}	Fermi energy [J, eV]
λ	Effective coupling constant [dimensionless]
Λ	Period of spin modulation [m]
ν	Landau level filling factor [dimensionless]
ρ	Charge density per unit length [Cm^{-1}]
ρ_{xy}	Hall resistivity [Ωm]
σ	Electronic spin [dimensionless]
σ_{coll}	Conductivity of collective mode [$\Omega^{-1} \text{m}^{-1}$]
σ_{xx}	Conductivity (diagonal) [$\Omega^{-1} \text{m}^{-1}$]
σ_{xy}	Hall conductivity [$\Omega^{-1} \text{m}^{-1}$]
τ	Relaxation time (transport) [s]
Φ	Free energy per unit cell [J^{-1} , eV^{-1}]
ϕ	Phase [radians]
χ	Spin susceptibility [dimensionless]
ψ	Electronic wave function [dimensionless]
ω_0	Pinning frequency [s^{-1}]
ω_{Λ}	Amplitudon frequency [s^{-1}]
ω_b	One-dimensional Fermi surface traversal frequency [s^{-1}]
ω_{m}	Magnon frequency [s^{-1}]
ω_{ϕ}	Phason frequency [s^{-1}]
l	One-dimensional Fermi surface traversal length [m]
$n(\varepsilon)$	Electronic density of states per unit cell [J^{-1} , eV^{-1}]

Introduction

A review of semiconductors would be incomplete without the inclusion of those classes of extremely narrow gap semiconductors and semimetals, that result from microscopic interactions between itinerant (or nearly free) electrons in a correlated metal. This section of the *Encyclopedia* is devoted to spin-density waves, which are a consequence of Coulomb interactions between electrons causing a system, which would otherwise be a conventional metal, to become antiferromagnetic (Blundell, 2001; Fawcett, 1988; Fawcett et al., 1994; Gruner, 1994, 1996; Kulikov and Tugushev, 1984). Perhaps the most extreme example is that where the Coulomb interactions between electrons exceeds the total electronic bandwidth, leading to an insulator that can be very well described by the Hubbard model. Spin-density waves are subtle by comparison, being much more dependent on details of the Fermi surface topology. It is therefore more convenient to consider spin-density waves as perturbations of electronic bands of quasiparticles in a metal. The gaps are significantly smaller, enabling quasiparticles to be easily excited across the spin-density wave gap, with tiny pockets of metallic carriers surviving in many cases.

The antiferromagnetism that results can often be mapped onto the simple case of a Heisenberg antiferromagnet (Gruner, 1996). The moments are nevertheless smaller with comparatively long spatial periodicities of the spin modulation projected in preferred crystallographic directions that are predetermined by the details of the bandstructure. The existence of thermodynamic coupling between the spin-density wave and charge degrees of freedom of the electronic bands causes these systems to be subject to phase excitations (or phasons) in a similar manner to charge-density wave systems (Gruner, 1996). Changes in the orientation of the spins, in contrast, take place via spin wave excitations (or magnons), which are qualitatively similar to those that occur in Heisenberg antiferromagnets.

We begin this chapter by considering the instability at the Fermi surface responsible for spin-density wave formation, and then continue by discussing their static and dynamic properties. These include collective excitations involving both electronic (phason) and spin (magnon) degrees of freedom (Gruner, 1996). Finally, we turn to the topic of field-induced spin-density waves in which orbital contributions to the total free energy help stabilize such ground states in the presence of a strong magnetic field. Transitions between different field-induced spin-density wave phases involving different levels of orbital quantization give rise to a novel manifestation of the bulk quantum Hall effect (Chaikin, 1996; Maki, 1986).

In general, the some of the formalisms that apply to a spin-density wave may also apply to density wave states involving other degrees of freedom where these other degrees of freedom can be presented as pseudospins. Possible examples include quadrupole-density waves in rare earth and actinide systems (Hafner et al., 2022), valley-density waves systems that exhibit a valley degeneracy (Schrade and Fu, 2019), or chirality-density waves (Kung et al., 2015).

Fermi surface nesting and spin-density wave formation

The term ‘spin-density wave’ refers to a simple one-dimensional (1D) antiferromagnetic modulation of the local spin density $\mathbf{S} = S_0 \cos(\mathbf{r} \cdot \mathbf{Q}_0 + \phi_0)$ condensed from electrons that subsequently become insulating (Blundell, 2001; Fawcett, 1988; Fawcett et al., 1994; Gruner, 1994, 1996; Kulikov and Tugushev, 1984). An essential precondition for spin-density wave formation to be energetically favorable is that a large fraction of the electron and hole quasiparticles share the same group velocity $\mathbf{v}_F$ at the Fermi energy ε_F . The residual Coulomb potential between quasiparticles U must also be significant, but smaller than the total electronic bandwidth W . These requirements tend to be more easily met in systems where the calculated electronic bands (i) are very narrow and (ii) are highly anisotropic or have large flat sections of Fermi surface that can efficiently nest. The term ‘nesting’ refers to the process by which the translational symmetry breaking of the crystalline lattice at a characteristic wavevector $\mathbf{Q}_0$ eliminates major sections of the Fermi surface upon opening a gap 2Δ . In a spin-density wave system, this gap opens up wherever spin-up and spin-down electronic bands cross. Fig. 1 shows an example of the cross-section of a Fermi surface amenable to nesting. The combined process of nesting and gap formation saves energy by greatly reducing the total electronic density of states at ε_F .

Fig. 1 An example of a fictional Fermi surface susceptible to nesting. The Fermi velocity $\mathbf{v}_F$ is always perpendicular to the Fermi surface. Translation of the Fermi surface by the nesting vector $\mathbf{Q}_0$ enables sections of Fermi surface with opposing Fermi velocities to meet each other tangentially. The nested sections become dielectric if the bands anticross upon opening of a gap. The dotted lines represent shadows of the translated Fermi surface.

Spin-density wave ground states occur most commonly in molecular or organic metals, although classic examples occur in elemental chromium and its alloys. The antiferromagnetic ground states of heavy fermion systems, which have quasiparticle effective masses many times the free electron mass, can also sometimes be understood in terms of spin-density waves. While many of these materials have complicated electronic structures, spin-density wave theory is most easily applied to systems with only a single quasi-one-dimensional electronic band

$$\varepsilon_{k,\sigma} = \hbar^2 k_x^2 / 2m + \varepsilon_\perp(k_y, k_z) + \sigma g \mu_B B \quad (1)$$

crossing ε_F . The simplest case, by far, is that for a metal where this band has a significant dispersion only along chains parallel to x , where k_x is the x component of the momentum vector $\mathbf{k}$ and $\sigma = \pm 1/2$ represents the up and down spin branches. A purely one-dimensional dispersion is obtained by setting the limit $\varepsilon_\perp(k_y, k_z) \rightarrow 0$. Because spin-density wave formation only involves states that are close to ε_F , it is often convenient to consider a linear approximation of the form

$$\varepsilon_{k,\sigma} = \hbar v_F |k_x - k_F| + \sigma g \mu_B B, \quad (2)$$

where $v_F = \hbar k_F / m$ at the 1D Fermi surface where $k = \pm k_F$. Theoretical models of spin-density waves regularly consider a dispersion of the form given by Eq. (2) in conjunction with a lattice spacing along x equal to $a = 2k_F / \pi$. This situation then corresponds to a half-filled band containing one electron per unit cell. There are two reasons why theoreticians make such a choice. One is that stoichiometric metals always contain an integral number of electrons per unit cell, where 1 is then the simplest number. The other is that half-filled bands facilitate direct comparisons with the Hubbard model, which can also yield antiferromagnetic ground states. In the present *Encyclopedia*, Eq. (2) is assumed to apply to more general band fillings. Fig. 2A shows a sketch of this dispersion relation for which $\varepsilon_\perp(k_y, k_z) \approx 0$ and the degeneracy of the spin-up and spin-down states is lifted by a finite B in order to demonstrate the independence of $Q_0 = 2k_F$ on magnetic field. Fig. 2B shows this same dispersion relation after undergoing translational symmetry breaking with respect to nesting vector and gap formation. The resulting multiple bands are obtained by solving

$$(2\varepsilon_\Delta - (\varepsilon_{k,\sigma} + \varepsilon_{nQ_0 - k,\sigma}))^2 - (\varepsilon_{k,\sigma} - \varepsilon_{nQ_0 - k,\sigma})^2 = 4\Delta^2 \quad (3)$$

For ε_Δ . The existence of a 1D Fermi surface enables perfect nesting in this case, giving rise to a fully gapped quasiparticle spectrum. Because spin-up and spin-down bands are entangled, spin is no longer a good quantum number for quasiparticle excitations across the gap.

Microscopic theory

The opening of the gap 2Δ can be formally described in terms of the Bardeen-Cooper-Schrieffer (BCS) theory that applies to superconductivity, but with the pairing occurring at a finite momentum $Q = Q_0$ between electron and hole quasiparticles of opposite spin (or electrons of like spin) (Gruner, 1994, 1996). The distinction between electrons and holes is purely a relative one, introduced to account for the fact that their group velocities oppose. In charge- and spin-density wave systems alike, the Fermi surface instability originates from a divergency in the Q -dependent charge and spin susceptibilities at $Q_0 = 2k_F$ which becomes logarithmic $\chi_0 \propto \ln |(Q + Q_0)/(Q - Q_0)|$ when the electronic dispersion is 1D as given by Eq. (2). Spin-density wave formation becomes increasingly favorable over charge-density wave formation when the spin susceptibility is enhanced by a Q -dependent Stoner factor, such that $\chi(Q) = \chi_0(Q)/(1 - U\chi_0(Q)/2\mu_0\mu_B^2)$. Because Q_0 is independent of magnetic field, spin-density waves are particularly robust in magnetic fields, and in some cases can even be strengthened, as will be shown to be the case for field-induced spin-density wave systems. For the dispersion relation given by Eq. (2) and Fig. 2A, mean field theory yields

$$\Delta_{T=0} = W e^{-\frac{1}{\lambda}} \quad (4)$$

at zero temperature, where $\lambda = Un(\varepsilon_F)$ is the effective coupling constant, and where $n(\varepsilon_F) \cong W^{-1}$ is the density of electronic states (per unit cell) at ε_F . The effective electronic bandwidth is $W = \pi \hbar v_F / a$ for the dispersion relation given by Eq. (2). As is the case for superconductivity, the transition into a spin-density wave phase is expected to be second order in the absence of an applied magnetic field and additional interactions, with the transition temperature T_{SDW} given by

Fig. 2 (A) The electronic dispersion according to Eq. (2) with a finite magnetic B included to lift the spin degeneracy. The up and down arrows indicate the spin-up and spin-down branches respectively, while Q_0 denotes the nesting vector. (B) The same bands, according to Eq. (3) after Fermi surface nesting and gap formation. The size of the gap at ε_F is 2Δ .

$$2\Delta \cong 3.52k_B T_{\text{SDW}} \quad (5)$$

in the weak coupling limit. The single particle electronic density of states becomes

$$n(\varepsilon) = W^{-1} \text{Re} \left\{ \frac{|\varepsilon - \varepsilon_F|}{\sqrt{(\varepsilon - \varepsilon_F)^2 - \Delta^2}} \right\} \quad (6)$$

upon opening a gap, which can be obtained by differentiating k_x in Eq. (3) with respect to energy ε . The spin-density wave condensation energy at zero temperature is given by

$$\Phi = -\frac{1}{2}n(\varepsilon_F)\Delta^2, \quad (7)$$

which is, again, similar to that in superconductivity. Since the present model considers only the case of a 1D dispersion, the coherence length is $\xi_0 = \hbar v_F / \pi \Delta$.

Basic static properties

In high quality samples at temperatures far below T_{SDW} , the correlation length over which the spin-density wave remains periodic greatly exceeds the coherence length (Gruner, 1994, 1996). It often follows that the low temperature, low electric field, low frequency conducting properties are those of a simple semiconductor or semimetal. In the case of the simple dispersion given by Eq. (2), perfect nesting leads to a classic semiconductor-like behavior of the conductivity.

$$\sigma_{xx} = \sigma_0 e^{-\Delta/k_B T}. \quad (8)$$

Ordinary quasiparticles must be thermally excited across the spin-density wave gap in order to contribute to the electrical conductivity, just as in a semiconductor. In metals with more complicated band structures, such as chromium, however, imperfect nesting leaves behind residual electron and hole pockets that continue to conduct in a conventional metallic fashion. In such a case, the electrical properties of the ground state are those of a semimetal, for which the conductivity contribution from quasiparticles excited across the spin-density wave gap is comparatively negligible. An important exception occurs in the case of magnetic field-induced spin-density waves, where the gap is augmented by a magnetic field as a consequence of Landau quantization.

The magnetic properties of spin-density waves are qualitatively similar to those of an antiferromagnet with a reduced moment

$$\mu = g\mu_B S = \frac{4\Delta}{U} \mu_B \quad (9)$$

and with a long period

$$\Lambda = \frac{2\pi}{Q_0} \quad (10)$$

that is matched to $2k_F$ rather than the crystalline lattice period a . The direction in which the spins preferentially align is determined by the effective coupling constants between them. The primary coupling constant for a simple 1D chain is given by

$$J = \hbar v_F \frac{(1 - \lambda)^{1/2}}{\Lambda} \quad (11)$$

in the weak coupling limit. If the spins order in a preferred direction orthogonal to the chains, the magnetic susceptibility $\chi_{\parallel}$ along that preferred direction is zero at temperatures $T \ll T_{\text{SDW}}$, provided the applied magnetic field is lower than that required to flop the spin. In other directions, the spins are able to cant, giving rise to a finite spin susceptibility $\chi_{\perp} = Ng^2\mu_0\mu_B^2/2VJ$, where V is the volume per unit cell.

In a similar manner to charge-density waves, the commensurability of a spin-density wave is determined by the number of electrons per unit cell, $N = Q_0 a / \pi$, where $2\pi/a$ is the length of the 1D Brillouin zone prior to ordering. If N can be accurately reduced to a simple fraction of the form $N = A/B$, where A and B here refer to integers, the superlattice period over which both the spin-density and atomic positions repeat is aB , in which case the spin-density wave is considered to be commensurate. The spin-density wave is incommensurate if N is an irrational number.

Collective excitations: Phonons

The close correlation between the periodicity of spin-density waves and the electronic structure near the Fermi energy implies that they can undergo charge excitations like charge-density waves (Gruner, 1994, 1996; Kulikov and Tugushev, 1984). These excitations then determine the electrodynamics of spin-density waves. It serves as a useful approximation to simplify the treatment of the

charge degrees of freedom by expanding the free energy in even powers of the order parameter and its spatial and temporal derivatives so as to obtain

$$\Phi = \alpha |\Delta|^2 + \beta \left(\frac{d\Delta}{dx} \right)^2 + \gamma \left(\frac{d\Delta}{dt} \right)^2. \quad (12)$$

Compatibility with the mean field theory is obtained by setting $\alpha = -n(\epsilon_F)/2$, $\beta = n(\epsilon_F)(\hbar v_F/2\Delta)^2$ and $\gamma = n(\epsilon_F)(\hbar/2\Delta)^2$. The order parameter itself can be expanded as

$$\Delta = (\Delta_0 + \delta)e^{i\phi} \quad (13)$$

where δ represents a small perturbation in its amplitude and $\phi = \mathbf{Q} \cdot \mathbf{r} = Qx$ accounts for the phase of the spin modulation described in the introduction. The dispersion relations for the excitation of the spin-density wave can then be obtained by assuming independent oscillatory variations $\delta = \delta_0 e^{i(\omega_A t - kx)}$ and $\phi = \phi_0 + \delta\phi e^{i(\omega_\phi - kx)}$ of the amplitude and phase of the spin-density wave respectively. Noting that the first two terms on the right-hand-side of Eq. (12) are potential energy terms while the third is a kinetic energy term, the application of Lagrangian mechanics yields

$$(\hbar\omega_A)^2 = 2\Delta^2 + (\hbar v_F k)^2 \quad (14a)$$

and

$$\omega_\phi = v_F k \quad (14b)$$

for the amplitude and phase modes respectively, which are sketched in Fig. 3. The first mode occurs at energies comparable to the gap. Since $S \propto \Delta$, this mode is effectively a high energy magnon mode. The second mode vanishes at $k = 0$, therefore corresponding to a collective sliding mode of the spin-density wave phase, which carries a dissipationless current analogous to the Fröhlich mode in charge-density wave systems. In practice, spin-density waves become strongly coupled to impurities and defects in the crystalline lattice, resulting in the opening of a small gap at $k = 0$. This inhibits dissipationless sliding, thereby restoring the familiar semiconducting properties of the spin-density wave state at low excitation energies.

The frequency dependent conductivity can be estimated by considering an electric field $E(t) = E_0 e^{i(\omega_\phi t - kx)}$, that then couples directly to the condensate charge. The equation of motion becomes

$$\frac{d^2 \phi}{dt^2} + v_F^2 \frac{d^2 \phi}{dx^2} = \frac{2k_F e E(\omega_\phi)}{m} \quad (15)$$

where

$$\rho = \frac{e}{\pi} \frac{d\phi}{dx} \quad (16)$$

is the accumulated electrical charge resulting from compression or tension of the spin-density wave and

$$j_{SDW} = \frac{e}{\pi} \frac{d\phi}{dt}, \quad (17)$$

is the electrical current resulting from its sliding motion. The solution of Eq. (15) yields a frequency-dependent conductivity of the collective mode of the form

$$\sigma_{\text{coll}}(\omega_\phi) = \frac{ne^2}{m} \left(\frac{\pi}{2} \delta(\omega_\phi) + \frac{i}{\omega_\phi} \right), \quad (18)$$

Fig. 3 Approximate dispersions relations of excitations of a simple spin-density wave ground state at low temperatures, ignoring the effects of impurities and magnetic anisotropy. ω_A is the amplitude mode, which effectively corresponds to high energy magnon excitations. ω_ϕ is the phason mode, corresponding to deformation and translational motion of the spin-density wave. ω_m is the magnon mode, corresponding to spin-waves involving purely rotational degrees of freedom of the spins.

where n is the carrier density (becoming N/a in one dimension) and $\delta(\omega_\phi)$ is a Dirac delta singularity. Since it does not include pinning interactions with impurities, which occur in real systems, this result is somewhat academic. Such interactions have two effects. The first is to bind the spin-density wave to the lattice, causing the Dirac delta singularity to be shifted to finite frequencies $\delta(\omega_\phi - \omega_0)$. The second is to resist the sliding motion of the spin-density wave causing losses that broaden the collective mode. This broadening can be phenomenologically modeled by considering an effective relaxation time τ . In spite of these complications, Eq. (18) is a useful result because an integration $(2/\pi) \int \sigma_{\text{coll}} d\omega_\phi$ of the conductivity over the frequency yields the same total spectral weight ne^2/m as is obtained in the normal metallic state. The implication of this result is that the spin-density wave collective mode is then able to account for all of the spectral weight. This contrasts with the case of a charge-density wave where coupling to the ionic lattice distortion causes the collective mode to acquire a heavy effective mass, reducing its share of the spectral weight.

A convenient means of modeling the effects of impurities on the frequency-dependent conductivity is to assume that the pinning forces dominate for small local perturbations of the spin-density wave position compared to the spin-density period $\Lambda = 2\pi/Q_0$, causing it to resonate about pinning sites at a characteristic frequency ω_0 . This can be formally accomplished by inserting a pinning restoring force $\omega_0^2 x$ and a damping term $(1/\tau)d\phi/dt$ into Eq. (15), and by assuming rigid motion of the spin-density wave whereby $v_F^2(d^2\phi/dx^2) = 0$. Hence,

$$\frac{d^2\phi}{dt^2} + \frac{1}{\tau} \frac{d\phi}{dt} + \omega_0^2\phi = \frac{2k_F e E(\omega_\phi)}{m}, \quad (19)$$

which facilitates a particularly trivial solution of the form

$$\sigma_{\text{coll}(\omega_\phi)} = \frac{ne^2}{i\omega_\phi m} \left(\frac{\omega_\phi^2}{\omega_0^2 - \omega_\phi^2 - i\omega_\phi/\tau} \right). \quad (20)$$

Owing to the simplifications made in Eq. (19), Eq. (20) can only be considered as an approximation. As well as not taking into consideration deformations of the phase, it also does not consider any details of the mechanism by which spin-density waves interact with impurities and defects. In the case of a charge-density wave, for example, the collective mode consists of a spatial modulation of the local charge, providing a direct means of coupling to charged impurities in the lattice. A spin-density wave must undergo relative phase shifts between its spin-up and spin-down components in order to realize a qualitatively similar type of coupling. In spite of these limitations, Eq. (20) provides a surprisingly good account of the frequency-dependent conductivity observed in most spin-density wave systems. The conductivity at yet higher frequencies then includes an additional resonance corresponding to quasiparticle excitations across the gap 2Δ , which is typically two to three orders of magnitude larger than ω_0 .

By taking appropriate limits, Eqs. (19) and (20) also provide us with a rough phenomenological understanding of the reaction of spin-density waves to a constant electric field. By setting $\omega_\phi = 0$ in Eq. (20), for example, we obtain zero conductivity, which is appropriate value for small values of the electric field E_0 at $T = 0$. By seeking a time-independent solution to Eq. (19), meanwhile, we can see that the spin-density wave will undergo continuous sliding motion provided the electric field exceeds a threshold value $E_0 > m\omega_0^2\phi/2ek_F$, where pinning force should eventually reverse and oscillate with x for $\phi > \pi/2$. This leads to a situation for large E_0 where the force of the electric field is balanced against the damping term, yielding a Drude-like conductivity.

Collective excitations: Magnons

In Eq. (14a), the amplitude of the spin-modulation can be seen to undergo excitations, but with a rather large gap 2Δ equivalent to that for quasiparticle excitations at $T = 0$ (Blundell, 2001; Gruner, 1994, 1996). Low energy magnon modes are not obtained from the simple model of the free energy given by Eq. (12), because it does not consider the rotational degrees of freedom of the spins that are necessary to produce spin waves. These can instead be obtained by mapping the spin degrees of freedom onto a simple 1D Heisenberg antiferromagnet Hamiltonian of the form

$$H = \left(\frac{\mu}{\mu_B} \right)^2 J \sum_p \mathbf{S}_{2p} \mathbf{S}_{2p+1} - g\mu_B \mathbf{B} \sum_p \mathbf{S}_{2p} + H_\perp. \quad (21)$$

Here, the prefactor accounts for the reduced moment, while the index p refers to a system with the periodicity Λ of reconstructed Brillouin zone rather than the original lattice. The magnetization is expected to be isotropic for isolated chains, in which case $H_\perp = 0$, leading to gapless spin wave behavior.

The equation of motion

$$\hbar \frac{d\mathbf{S}_{p+1}}{dt} = \mathbf{m} \times \mathbf{B}_{\text{eff}} \quad (22)$$

for spin waves is obtained by equating the rate of change of angular momentum against the torque imposed on spins rotated with respect to each other along the chain. Here, $\mathbf{m} = \mu\mathbf{g}\mathbf{S}$ is the reduced moment expressed in vector form to account for its orientation. Since we are dealing with an antiferromagnet, the total effective molecular field

$$\mathbf{B}_{\text{eff}} = (-1)^q \frac{J}{g\mu_B} (\mathbf{S}_{2p+q-1} + 2\mathbf{S}_{2p+q} + \mathbf{S}_{2p+q+1}) \quad (23)$$

felt by each moment due to its two nearest neighbors alternates between odd and even q sites. The solution to Eq. (22) is well known to have the form

$$\hbar\omega_m = 2JS \left| \sin \frac{\Lambda k}{2} \right|, \quad (24)$$

where $\Lambda/2$ is the effective separation between spins along the chain. The dispersion relation given by Eq. (24) is sketched in Fig. 3, along with the other modes, and can be seen to be approximately linear at low excitation energies.

In real spin-density wave systems, the crystal extends in three dimensions, leading to the possibility of additional couplings between the chains. Should the spins then have preferred axes of orientation, the antiferromagnet becomes anisotropic. The spins may no longer be free to rotate under such circumstances, causing the linear dispersion given by Eq. (24) to become gapped. These effects are usually modeled by considering the anisotropy term $H_{\perp}$ in Eq. (21) to include contributions that increase or reduce the energy D associated with the alignment of spins along certain directions. The size of the gap is typically of order $2S\sqrt{D}$.

Field-induced spin-density waves

Eq. (3), as depicted in Fig. 2A, yields a set of bands that change with magnetic field, but where the gap in the density of electronic states at ε_F remains symmetric about ε_F (Chaikin, 1996; Maki, 1986). This occurs because the spin-density waves are the consequence of pairing between electron and hole quasiparticles of opposite spin, causing simple spin-density wave systems to be independent of a magnetic field. This situation changes, however, as soon as the nesting becomes imperfect. Imperfect nesting leaves behind small pockets of Fermi surface that then undergo orbital quantization in a magnetic field. Orbital quantization has a pronounced effect on the free energy of the total system at low temperatures, providing an additional source of energy that can help make the spin-density wave ground states more stable in a magnetic field. Such effects should occur in all spin-density wave systems with imperfect nesting, including elemental chromium, but are more pronounced in systems where the transition temperature into the spin-density wave phase is low, or where the electronic bands are highly anisotropic. By far the most striking behavior occurs in systems with an incipient spin-density wave, as has been shown to be the case in certain examples of the Bechgaard salts. By “incipient” we mean that the Coulomb interactions are present to the extent that the metal is on the threshold of forming a spin-density wave phase, but where the efficiency of the nesting is insufficient to make a spin-density wave ground state stable at zero magnetic field. The system then has the potential to undergo transitions into spin-density wave phases in a magnetic field; hence the term “field-induced spin-density waves.” At zero magnetic field, the ground state can be a normal metal or a superconductor. The spin-density wave phase supersedes superconductivity in a magnetic field, simply because superconductivity is inhibited by magnetic fields.

One way to understand the origin of field-induced spin-density waves is through the process of one-dimensionalization of the electron motion in a magnetic field. A simple model to consider is that where the k_y component of the electronic dispersion given by Eq. (1) has the form

$$\varepsilon_{\perp}(k_y) = -2t_b \cos k_y b - 2t'_b \cos 2k_y b, \quad (25)$$

where $t_b < W/4$ and $t'_b < t_b$ are the nearest neighbor and second nearest neighbor electron transfer energies along the b axis of a crystal. As shown in Fig. 4A, the Fermi surface can no longer be nested by $\mathbf{Q}_0 = (2k_F, 0)$ or $\mathbf{Q}_0 = (2k_F, \pi/b)$ owing to the finite values of the transfer integrals along b . A magnetic field causes electrons on the two-dimensional Fermi surface to follow a snake-like path like that in Fig. 4B, where its real space width $4bt_b/\hbar\omega_b$ and period $l = 2\pi v_F/\omega_b$ decrease inversely proportionately with the frequency

Fig. 4 (A) A sketch of a Fermi surface like that found in the Bechgaard salts, in which the nesting at vector $\mathbf{Q}_0$ is imperfect. The dotted lines show what the Fermi surface looks like when $\varepsilon_{\perp}(k_y) = 0$, whereupon perfect nesting is recovered. Arrows indicate the direction of motion of quasiparticles on the Fermi surface for a magnetic field pointing out of the page. (B) The trajectory of a quasiparticle in real space, obtained through the equation of motion, $\hbar d\mathbf{k}/dt = e\mathbf{v}_F \times \mathbf{B}$, where $\mathbf{v}_F = \nabla_{\mathbf{k}} \varepsilon(\mathbf{k})$. The spatial dimensions of the real space trajectory are inversely proportional to the magnetic field strength. The product lb encloses a single flux quantum.

$\omega_b = eBv_F b / \hbar$, and hence the magnetic field B . One can make that qualitative argument that the motion becomes 1D as soon as $4t_b < \hbar\omega_b$, whereupon quasiparticles are mostly confined to single 1D chains.

From the quantum mechanical perspective, the one-dimensionalization can be understood by making a Landau-Peierls substitution, $\mathbf{k} \rightarrow i \nabla = e\mathbf{A}/\hbar$, into the dispersion relation given by Eqs. (1) and (25). This yields a 1D Schrödinger equation,

$$\frac{\hbar^2}{2m} \frac{d^2}{dx^2} \psi(x) - 2t_b \cos\left(k_y - \frac{2\pi}{l}x\right) - 2t'_b \cos\left(2k_y b - \frac{4\pi}{l}x\right) = \varepsilon \psi(x), \quad (26)$$

that is a function only of x where k_y then merely determines the shift in the coordinate of the center of the wavefunction.

Spin-density wave formation now involves the nesting of ε as determined by Eq. (26). In spite of the added complexity, the thermodynamics is shown to be surprisingly similar to that of a conventional spin-density wave ground state. Notably, Eqs. (4), (5) and (7) continue to apply, but with the effective coupling constant having a modified form

$$\lambda = Un(\varepsilon_F)J_0^2\left(\frac{2t'_b}{\omega_b}\right), \quad (27)$$

Where J_0 is a zeroth order Bessel function. The electronic density of states continues to be fully gapped, but where 2Δ also functions as a Landau gap between Landau bands dispersed with respect to k_x , in which the orbital motion of quasiparticles is quantized. The orbital angular momentum of each quasiparticle in each Landau band is given by $\hbar(v + \frac{1}{2})$ where the quantum number has values $v = 0, 1, 2 \dots$ as for Landau levels in a simple two-dimensional electron gas. The Landau bands are each separated in energy by an effective cyclotron energy $\hbar\omega_c$ that depends on the details of the nested band structure. By making an analogy with two-dimensional electron gas systems, we gain further insight into understanding why imperfectly nested spin-density waves are stabilized by a magnetic field. The free energy of a two-dimensional electron gas experiences sharp minima as a function of B whenever ε_F is situated in a Landau gap (i.e. somewhere in the gap between two adjacent Landau levels v and $v + 1$). It is by utilizing such minima between Landau bands that field-induced spin-density waves become stable. This therefore exacts a constraint by which ε_F must always be situated within a Landau gap in a field-induced spin-density wave phase.

The above constraint has two important implications for field-induced spin-density wave systems. The first is that the Landau bands are always completely filled, giving rise to a type of integer quantum Hall effect where

$$\sigma_{xy} = \pm \frac{2ve^2}{h} \quad (28)$$

per layer, where v is the quantum number of the highest occupied Landau level and where the sign depends on whether the one or two closed pockets contain a net number of electrons or holes. The second implication is that the nesting vector is quantized, where

$$Q_0 = \left(2k_F \pm \frac{2\pi v}{l}, \frac{\pi}{b} + \delta k_y\right) \quad (29)$$

in the simplest case, in order to sustain an integer filling factor v . This type of quantum Hall effect differs from that in conventional two-dimensional electron gas systems in several ways. The first is the factor of 2 in the numerator of Eq. (28), which results from the fact that up and down-spin states are paired with no net spin quantum numbers, giving rise to completely spin-degenerate Landau bands. The second is that the net slope of the Hall resistivity $\rho_{xy} = 1/\sigma_{xy}$ throughout the field-induced spin-density wave phases, depicted in Fig. 5, does not intersect $\rho_{xy} = B = 0$. Finally, the quantum Hall effect does not depend on the existence of localized states in the tails of Landau levels as it does in conventional two-dimensional electron gas systems. The inability of ε_F to reside in a Landau band implies that a change in the value of the quantized Hall conductivity must be realized by means of a first order phase transition between phases with different optimal values of v . An alternative possibility is that the normal metallic phase is restored between stable Hall plateaux. Orbital quantization within field-induced spin-density wave phases causes the off-diagonal components of the conductivity tensor to dominate over the diagonal ones, giving rise to a low resistivity state, $\rho_{xx} \sim \sigma_{xx}/\sigma_{xy}^2 \rightarrow 0$, as in the conventional quantum Hall effect. This contrasts with the semiconductor-like behavior seen in perfectly nested spin-density wave phases.

Fig. 5 A plot of the Hall resistivity (per layer) of a field-induced spin-density wave system versus magnetic field, exhibiting quantized Hall plateaux. Sharp changes are expected to occur between different states characterized by different values of v owing to the first-order nature of the transitions.

Conclusion

Spin-density waves are a type of antiferromagnetic modulation of the local spin density in a correlated metal. They result from interactions between itinerant electrons and can cause a metal to become insulating. Spin-density waves are characterized by a one-dimensional modulation of the spin density and can be described by the Bardeen-Cooper-Schrieffer (BCS) theory. They are most commonly observed in molecular or organic metals, as well as in elemental chromium and its alloys.

The formation of spin-density waves is favored when a large fraction of electron and hole quasiparticles have the same group velocity at the Fermi energy and when the Coulomb potential between quasiparticles is significant but smaller than the electronic bandwidth. Spin-density wave formation is facilitated in systems with narrow and anisotropic electronic bands that can efficiently “nest” upon opening a gap in the electronic density of states. The spin-density wave gap opens wherever spin-up and spin-down electronic bands cross, and the energy gap can be described by the BCS theory.

The properties of spin-density waves include collective excitations involving both electronic (phason) and spin (magnon) degrees of freedom. The stability and behavior of spin-density waves are influenced by magnetic fields, and field-induced spin-density waves can exhibit novel phenomena such as the bulk quantum Hall effect. Spin-density waves can also be commensurate or incommensurate, depending on the number of electrons per unit cell.

In terms of static properties, spin-density waves exhibit semiconductor-like behavior in high-quality samples at low temperatures, where thermal excitation is required for quasiparticles to contribute to electrical conductivity. The magnetic properties of spin-density waves are similar to those of antiferromagnets, with a reduced magnetic moment and a long period determined by the effective coupling constants. The spin alignment is influenced by the direction of preferred coupling.

Overall, spin-density waves play a significant role in understanding the behavior of correlated metals and their magnetic properties. They offer insights into the interplay between electronic structure, magnetism, and collective excitations in condensed matter systems.

Abstract

An overview of the physics of free carriers, electrons in the conduction band and holes in the valence band, is presented focusing on how they affect the electronic properties of semiconductors. Electron and hole pockets, and the corresponding effective masses, are illustrated for several key semiconductors. Doping, conductivity, mobility, Hall effect and cyclotron resonance are discussed.

Key points

- The shape of the electron and hole pockets are described for the most important semiconductors.
- The role of intentional doping via donors and acceptors is discussed.
- The behaviour of the free carrier density as a function of temperature and doping level is shown.
- The carrier mobility as due to different scattering mechanisms is described.
- The electrical conductivity and its dependence on temperature and doping level is discussed.
- Excitons and trions are briefly introduced.

Introduction

The paramount role of semiconductors in today's technology since the invention of the transistor consists mainly in their use in electronic devices, particularly very large scale integrated circuitry, in which electric currents are due to mobile electrons and holes. The possibility of growing single crystals of very high purity and to control their transport properties through intentional n-type and p-type doping has been crucial to the development of the electronic industry. Silicon is presently the material of choice for electronic devices not only because of its outstanding processing properties, but also because its native oxide forms a high quality semiconductor-insulator interface. Semiconductors have at the same time attracted a lot of attention from the viewpoint of basic science, and understanding their electronic structure, optical and transport properties has been a great success of solid state physics (Bassani and Pastori Parravicini, 1975; Yu and Cardona, 1995).

The resistivity of semiconductors is intermediate between that of metals and insulators, varying at room temperature between 10^{-4} and 10^{10} Ω cm, and is extremely sensitive to the presence of impurities. The value of the resistivity is not the best criterium defining a semiconductor, but rather the property that in pure enough samples the resistivity decreases with increasing temperature in a way that is exponential with the inverse temperature (intrinsic regime). Another property of semiconductors is that not only the electrons, but also positive charge carriers, i.e., the holes, may be responsible for electrical conductivity, as shown by the sign of the Hall coefficient. Finally, it is of crucial technological importance the possibility to control the carrier concentration by intentional doping (extrinsic regime).

Semiconductors are characterized by an energy gap of the order of the electronvolt separating the highest occupied band (the valence band) from the lowest unoccupied one (the conduction band); the former may be populated by mobile holes (corresponding to missing electrons), the latter by mobile electrons. In the following, the behavior of electrons and holes in

[☆]*Change History:* September 2022. GC La Rocca (original author) prepared the update. New paragraph on IV-VI semiconductors and new Table 1 are added. New section Electron-hole complexes. Very minor amendments (mostly typos) elsewhere.

homogeneous semiconductors will be described considering relevant electronic band structure properties, doping and equilibrium carrier concentration, mobility and electrical conductivity (Landolt-Börnstein, 1982; Seeger, 1991; Singh, 1994; Sze, 1985).

Electron and hole pockets

The transport properties of semiconductors are dominated by carriers (electrons and holes introduced by doping or excited across the energy gap) which occupy the bottom of the conduction band or the top of the valence band. An accurate description of the electronic energy bands near these extrema is usually obtained employing the $\vec{k} \cdot \vec{p}$ perturbative method. Then, the response of the carriers to external perturbations, such as electric and magnetic fields, slowly varying on the scale of the lattice constant can be dealt with using the effective mass approximation.

The $\vec{k} \cdot \vec{p}$ method consists of a perturbative calculation of the electronic states with a Bloch wave vector $\vec{k}$ close to a given $\vec{k}_0$ point (usually of high symmetry) in the Brillouin zone (BZ) corresponding to a maximum in the valence band (hole pocket) or a minimum in the conduction band (electron pocket). For a non-degenerate band, as typical for electrons, a single band approximation is usually employed, the interaction with all other bands being treated in perturbation theory up to second order in $(\vec{k} - \vec{k}_0)$. In this case, one gets simply:

$$E(\vec{k}) = E(\vec{k}_0) + \frac{\hbar^2}{2} (\vec{k} - \vec{k}_0) \cdot \vec{m}^{-1} \cdot (\vec{k} - \vec{k}_0), \quad (1)$$

where the inverse effective mass tensor $\vec{m}^{-1}$ for the extremum of interest has been introduced. Finally, measuring the energy from $E(\vec{k}_0)$ and the wavevector from $\vec{k}_0$, and choosing the $\hat{1}, \hat{2}$ and $\hat{3}$ directions along the principal axes of $\vec{m}^{-1}$, the standard expression for ellipsoidal pockets is obtained:

$$E(\vec{k}) = \frac{\hbar^2}{2} \left(\frac{k_1^2}{m_1} + \frac{k_2^2}{m_2} + \frac{k_3^2}{m_3} \right). \quad (2)$$

Then, in the presence of slowly varying external perturbations, the dynamics of the electrons in a conduction band minimum can be described as that of free carriers (i.e., without considering the rapidly varying crystal potential) with a positive (anisotropic) effective mass and a negative charge e . In particular, they will give rise to a current in the same direction of the applied electric field while moving in the opposite direction. Likewise, a hole pocket is associated to a maximum in the valence band and is characterized by negative values of the effective mass parameters appearing in Eq. (2). Such states which in a pure crystal at zero temperature are completely occupied may become empty and, upon the action of an applied electric field, give rise to a current that can be thought of as due to positively charged particles with a positive (anisotropic) effective mass. This is so because instead of considering the motion of the very large number of electrons which fill almost the entire valence band, it is convenient to focus on the dynamics of the few empty states whose electrons are missing, i.e., the hole states. As the energy of a hole state increases when the energy of the corresponding missing electron decreases, in the hole picture used in the following, the sign of the effective mass parameters of a hole pocket will be taken as positive and at the same time the charge of a hole as $+e > 0$. A hole moves in the same direction of the applied electric field and contributes to a current in the same direction.

The symmetry of the dispersion relation of electron (or hole) pockets as well as the values of the corresponding effective mass parameters can be measured by cyclotron resonance, i.e., the absorption of radio-frequency radiation in the presence of an external magnetic field $\vec{B}$. The resonance frequency is $\omega_c = (eB/m^*(\vec{B})c)$, with

$$m^*(\vec{B}) = \sqrt{\frac{m_1 m_2 m_3}{m_1 (\hat{B} \cdot \hat{1})^2 + m_2 (\hat{B} \cdot \hat{2})^2 + m_3 (\hat{B} \cdot \hat{3})^2}}. \quad (3)$$

From the dependence of the observed absorption on the magnitude and direction of the magnetic field, the symmetry of the pockets of carriers as well as their effective mass parameters can be determined. Also magnetoresistance measurements are sensitive to the mass anisotropy and other band structure features, in particular from the strong dependence on the current and magnetic field directions with respect to the cubic axes, the symmetry of the carrier pockets involved can be identified, similarly to the case of cyclotron resonance measurements.

The conduction band of Ge has four electron pockets at the L point of the BZ (see Fig. 1; the half pockets at $\vec{k}$ and $-\vec{k}$ are to be combined together); they are ellipsoids of revolution elongated along the $\langle 111 \rangle$ directions. The values of the longitudinal mass $m_L = m_3 \simeq 1.6m$ and of the transverse mass $m_T = m_1 = m_2 \simeq 0.08m$ have been determined from cyclotron resonance measurements such as those shown in Fig. 2 (Dresselhaus et al., 1955): with $\vec{B}$ along $[\sqrt{3}/\sqrt{2}, \sqrt{3}/\sqrt{2}, 1]/2$ the four $\langle 111 \rangle$ electron pockets split into three groups inequivalently oriented with respect to the magnetic field, each one of these giving rise to a distinct resonance according to Eq. (3). The conduction band of Si has six electron pockets along the $\langle 100 \rangle$ directions (see Fig. 3); they are ellipsoids of revolution elongated along the same directions with a longitudinal mass $m_L = m_3 \simeq 1.0m$ and a transverse mass $m_T = m_1 = m_2 \simeq 0.08m$ (measured from cyclotron resonance, see Fig. 4 (Dresselhaus et al., 1955) where due to the choice of

Fig. 1 Electron pockets in Ge.

Fig. 2 Cyclotron resonance in Ge (at a frequency of 24 GHz and a temperature of 4 K) with magnetic field in the (110) plane at 60° from the [001] axis. From Dresselhaus, G. Kip, AF, Kittel, C (1955) *Physics Review* 98: 368.

magnetic field orientation two distinct electronic resonances show up). Typical zinc-blende semiconductors have a simple electron pocket at the center of the BZ (Γ point) with an isotropic effective mass; for instance, the electron effective mass of GaAs is $0.067 m$.

The hole pockets in Si, Ge and typical zinc-blende semiconductors are at the center of the BZ and correspond to a three-fold p-like degenerate band (without spin) that splits due to the spin-orbit interaction into an upper fourfold degenerate ($J = 3/2$) band and a lower two-fold degenerate ($J = 1/2$) band (spin included). The former corresponds to the top of the valence band and the latter to the split-off valence band which, apart from spin, is non degenerate. The split-off hole states can be described as a simple band with an isotropic effective mass $m_{so} \simeq 0.25 m$ in Si, $m_{so} \simeq 0.08 m$ in Ge, $m_{so} \simeq 0.2 m$ in GaAs. In a rough approximation, the topmost hole states can be described as belonging to two distinct spherical pockets each characterized by an isotropic mass: the heavy hole pocket (with mass $m_{hh} \simeq 0.5 m$ for Si, $m_{hh} \simeq 0.3 m$ for Ge, $m_{hh} \simeq 0.5 m$ for GaAs) and the light hole pocket (with mass $m_{lh} \simeq 0.16 m$ for Si, $m_{lh} \simeq 0.044 m$ for Ge, $m_{lh} \simeq 0.09 m$ for GaAs). Also the hole masses have been determined from cyclotron resonance measurements such as those shown in Fig. 2 and Fig. 4. A complete description of the hole states beyond this simple picture could only be given within a multi-band $k \cdot p$ approach, in which the valence band degeneracy is fully accounted for.

Another important class of semiconductors are the narrow gap IV-VI lead-salts (PbTe, PbSe, PbS) which crystallize in the rocksalt cubic structure. They are characterized by a direct gap at the edge of the Brillouin zone along the [111] direction (i.e., the *L* point). The small gap (about 0.2 eV) and the symmetry of the conduction and valence bands make the four electron pockets almost identical to the four hole pockets in these semiconductors (and both similar to the Ge electron pockets shown in Fig. 1). The respective longitudinal and transverse effective masses for electrons and for holes are given in Table 1 (from de Andrada e Silva, 1999).

Donors and acceptors

The ability to control the content of impurities is a key issue in semiconductor technology: the concentration of undesired dopants in Si is typically kept below 10^{12} cm^{-3} . A foreign atom may give rise to electronic states, more or less localized around the impurity site, with energies lying in the forbidden energy gap of the host material. The impurity levels may either be close to the conduction or valence band edges (shallow donor or acceptor states) or to the middle of the gap (deep states). In the first case, they behave as dopants and dominate the transport properties providing extrinsic free carriers; in the second case, they mainly affect the recombination of free electron-hole pairs by trapping them at the same site.

Depending on their chemical valency, foreign atoms typically used as dopants may provide one extra electron or one extra hole (i.e., one missing electron) with respect to the host atoms they replace. For instance, a group V impurity, say P, substituting a group IV host atom, such as Si, provides an extra electron to the crystal (donor behavior), while a substitutional group III impurity, say B, at the same site would provide an extra hole (acceptor behavior). The extra hole or electron, with respect to the fully occupied valence band, is bound to the defect site by the long range Coulomb potential due to the charge difference between the impurity and host nuclei. Because of the low effective masses ($m^* \simeq 0.2 m$) and the high dielectric constants ($\epsilon \gtrsim 10$) typical of semiconductors, the corresponding localized states extend over many unit cells and may be described within the effective mass approximation as a solid state analogue of the hydrogen atom with scaled down Rydberg energy $R^* = (m^* e^4 / 2 \hbar^2 \epsilon^2)$ and Bohr radius $a^* = (\hbar^2 \epsilon / m^* e^2)$ ($R^* \simeq 20 \text{ meV}$, $a^* \simeq 50 \text{ \AA}$). As their binding energy is small, such impurity levels are shallow, i.e., close to the bottom of the conduction band for the case of donors and close to the top of the valence band for the case of acceptors. Thus, they are easily thermally ionized providing free electrons to the conduction band (n-type doping) or free holes to the valence band (p-type doping), as discussed below.

Free carrier density

According to the Boltzmann distribution law (valid at typical carrier concentrations and temperatures, i.e., excluding the case of quantum degeneracy), the density n of electrons in the conduction band and of holes p in the valence band can be expressed as

$$n(T, \mu) = N_c(T) \exp((\mu - E_c)/k_B T) \quad (4)$$

$$p(T, \mu) = N_v(T) \exp((E_v - \mu)/k_B T) \quad (5)$$

with a chemical potential μ well inside the energy gap between E_v and E_c (the top of the valence band and the bottom of the conduction band, respectively), being $N_c = \left(\frac{K_B T}{\pi \hbar^2}\right)^{3/2} \frac{(m_c^{(D)})^{3/2}}{\sqrt{2}}$ and $N_v = \left(\frac{k_B T}{\pi \hbar^2}\right)^{3/2} \frac{(m_v^{(D)})^{3/2}}{\sqrt{2}}$, where $m^{(D)}$ is the density of states effective mass given for a many-valley conduction band by an average over the equivalent valleys $m_c^{(D)} = g^{2/3} (m_T^2 m_L)^{1/3}$, g being the valley degeneracy (6 for Si, 4 for Ge), and for the valence band by an average over heavy and light holes $m_v^{(D)} = (m_{lh}^{3/2} + m_{hh}^{3/2})^{2/3}$. The densities of electrons and holes in thermal equilibrium at temperature T satisfy the law of mass action

$$np = N_c N_v e^{-E_g/k_B T}. \quad (6)$$

In a pure (intrinsic) semiconductor, the density of electrons n_i thermally excited into the conduction band equals the density of holes p_i left behind in the valence band and they are given by

$$n_i = p_i = \sqrt{N_c N_v} \exp(-E_g/2k_B T);$$

the intrinsic concentration of carriers is dominated by the exponential dependence on $E_g/(2k_B T)$. For instance, one obtains at room temperature for Si $E_g = 1.1 \text{ eV}$, $N_c \simeq 3 \cdot 10^{19} \text{ cm}^{-3}$, $N_v \simeq 1 \cdot 10^{19} \text{ cm}^{-3}$, $n_i = p_i \simeq 1.5 \cdot 10^{10} \text{ cm}^{-3}$; for Ge $E_g = 0.66 \text{ eV}$, $E_g = 0.66 \text{ eV}$, $N_c \simeq 1 \cdot 10^{19} \text{ cm}^{-3}$, $N_v \simeq 6 \cdot 10^{18} \text{ cm}^{-3}$, $n_i = p_i \simeq 2.3 \cdot 10^{13} \text{ cm}^{-3}$; for GaAs $E_g = 1.43 \text{ eV}$, $N_c \simeq 4.4 \cdot 10^{17} \text{ cm}^{-3}$, $N_v \simeq 8 \cdot 10^{18} \text{ cm}^{-3}$, $n_i = p_i \simeq 2 \cdot 10^6 \text{ cm}^{-3}$. For the non-degenerate regime here considered, the intrinsic Fermi level (chemical potential) is given by $\mu_i = (E_c + E_v)/2 + (3/4) k_B T \ln(m_v^{(D)}/m_c^{(D)})$, and is close to the center of the gap (i.e., $(E_c + E_v)/2$).

In a doped semiconductor with a concentration of donors N_d and of acceptors N_a , if $N_d > N_a$ (n-type) the electron (majority carrier) density is approximately $n = N_d - N_a$ and the hole (minority carrier) density is correspondingly $p = (n_i p_i)/n$; if $N_d < N_a$ (p-type) similar formulas hold with the role of majority and minority carriers interchanged. In n-type semiconductors the chemical potential μ is shifted a bit closer to E_c with respect to μ_i , as given by

$$\frac{N_d - N_a}{2n_i} = \sinh\left(\frac{\mu - \mu_i}{k_B T}\right); \quad (7)$$

the converse is true for p-type semiconductors. In the above, the temperature has been assumed to be high enough to ionize all the impurities, but not so high that the concentration of intrinsic carriers (i.e., those thermally excited across the energy gap) should

Fig. 5 Temperature dependence of majority carrier concentration in n-doped Si ($N_d = 10^{15} \text{ cm}^{-3}$). The intrinsic carrier concentration is shown by the dashed line for comparison.

be comparable to the majority carrier concentration. In this case, i.e., the extrinsic regime, the carrier concentration is independent of temperature and determined by the doping level. At lower temperatures, the concentration of ionized impurities decreases because more and more electrons fall in the impurity bound states and the concentration of free carriers drops (freeze-out regime). The typical temperature dependence of the majority carrier concentration in a doped semiconductor over a wide temperature range is depicted in Fig. 5. The wide plateau (extrinsic regime) around room temperature shows how the carrier concentration can be suitably fixed by intentional doping, a characteristic semiconductor behavior of paramount importance for electronic applications.

Carrier mobility and electrical conductivity

In a cubic semiconductor, the low field conductivity tensor relating the current density $\vec{j}$ to the electric field $\vec{E}$ is a scalar $\vec{j} = \sigma \vec{E}$ given by

$$\sigma = e(n\mu_n + p\mu_p), \quad (8)$$

where n and p are the densities of conduction band electrons and valence band holes, respectively, and μ_n and μ_p the corresponding mobilities, relating the average drift velocities of electrons or holes to the electric field, given by

$$\mu_{n,p} = \left(e/m_{n,p}^{(\sigma)} \right) \tau_{n,p}, \quad (9)$$

where $m^{(\sigma)}$ the appropriate effective mass and $\tau_{n,p}$ the appropriate momentum relaxation time as determined by the scattering mechanisms briefly discussed below. For a many-valley band extremum, such as for the electron pockets in Si and Ge, the conductivity effective mass to be used above is an average given by

$$1/m_n^{(\sigma)} = (2/m_T + 1/m_L)/3, \quad (10)$$

and n is the total density of electrons equally distributed among the equivalent valleys. From the values of the electron transverse and longitudinal masses, one obtains for Si $m_n^{(\sigma)} \simeq 0.27m$ and for Ge $m_n^{(\sigma)} \simeq 0.12m$. When more than one electron or hole bands are populated, e.g., light and heavy hole bands, their contributions add up in the above expression for σ . The conductivity of a semiconductor, in contrast to that of a metal, varies strongly because of the dramatic dependence of the electron and hole densities on the temperature and the doping level; only a smoother variation is brought about by mobility changes. The carrier mobilities are related to the respective diffusion coefficients by the Einstein relation $e D_{np} = \mu_{np} k_B T$.

At room temperature, in pure or moderately doped elemental semiconductors, the mobility is limited mainly by phonon scattering, whereas, at lower temperatures or heavy doping levels, the ionized impurity scattering is dominant. In nonpolar semiconductors such as Si and Ge, the main electron-phonon scattering mechanism is due to longitudinal acoustic phonon deformation potential scattering with a scattering rate $1/\tau_{ac}$ depending on temperature like $T^{3/2}$. However, significant deviations from this behavior are observed, mostly due to the mixture of acoustic and optical phonon scattering. In zinc-blende

semiconductors such as GaAs, at room temperature the main scattering mechanism is due to polar longitudinal optical phonon scattering with a stronger dependence on temperature. The mobility values in pure materials at room temperature are for Si $\mu_n \simeq 1500 \text{ cm}^2/(\text{Vsec})$, $\mu_p \simeq 500 \text{ cm}^2/(\text{Vsec})$; for Ge $\mu_n \simeq 3900 \text{ cm}^2/(\text{Vsec})$, $\mu_p \simeq 1900 \text{ cm}^2/(\text{Vsec})$; for GaAs $\mu_n \simeq 8500 \text{ cm}^2/(\text{Vsec})$, $\mu_p \simeq 400 \text{ cm}^2/(\text{Vsec})$. The impurity Coulomb scattering rate $1/\tau_{inv}$ instead, is proportional to $T^{3/2} N_{inv}$, being N_{im} the density of ionized impurities. Experimentally, it is not easy to see the $T^{3/2}$ dependence of the impurity scattering limited mobility as the temperature range in which this mechanism is dominant is restricted at low temperatures by the carrier freeze-out and at high temperatures by the onset of phonon scattering. However, when more sources of scattering are competing the total resistivity is approximately given by the sum of the resistivities obtained from each single scattering mechanism at a time (Matthiessen's rule). As a result, the mobility of doped semiconductors may exhibit a maximum at the temperature corresponding to the crossover from impurity scattering to phonon scattering. Such a behavior is evident in Fig. 6 and Fig. 7 which show, respectively, the electron mobility in Si and GaAs vs. temperature for various doping levels.

The temperature dependence of the conductivity of Si at different doping levels is shown in Fig. 8 (Morin and Maita, 1954). The intrinsic regime is evident over most of the temperature range; the flattening of some of the curves at about room temperature corresponds to the extrinsic regime in which the conductivity is determined by the doping level. The temperature dependence of σ is

Fig. 6 Temperature dependence of mobility in n-type Si at various doping levels: (1) $N_d < 10^{12} \text{ cm}^{-3}$ (high purity), (2) $N_d < 10^{13} \text{ cm}^{-3}$ (high purity), (3) $N_d = 1.6 \cdot 10^{16} \text{ cm}^{-3}$, (4) $N_d = 1.3 \cdot 10^{17} \text{ cm}^{-3}$. From the database NSM maintained by the Ioffe Institute.

Fig. 7 Temperature dependence of mobility in n-type GaAs at various doping levels: top curve $N_d = 5 \cdot 10^{14} \text{ cm}^{-3}$, middle curve $N_d = 10^{15} \text{ cm}^{-3}$, bottom curve $N_d = 5 \cdot 10^{15} \text{ cm}^{-3}$. From the database NSM maintained by the Ioffe Institute.

Fig. 8 Temperature dependence of conductivity in Si at various doping levels. From Morin EJ and Maita JP (1954) *Physics Review* 94: 1525.

dominated by that of the carrier concentration in the intrinsic regime, whereas its weaker variation in the extrinsic regime is due to the temperature dependence of the mobility.

Measuring the Hall coefficient is a widely used method to characterize the concentration (and type) of free carriers; the Hall coefficient R_H is given by

$$R_H = \frac{p\mu_p^2 - n\mu_n^2}{ce(p\mu_p + n\mu_n)^2}. \quad (11)$$

In weak fields, the mobilities appearing in the numerator of the above expression are in general to be multiplied by corrective factors of order unity (i.e., the ratios of Hall mobilities to drift mobilities: μ_H/μ) which depend on the scattering mechanism and the band structure details. Notice that in p-type samples the sign of R_H is positive, i.e., opposite to that of n-type samples.

So far we have considered the low field conductivity corresponding to the ohmic regime. With increasing field strength, the free carrier drift velocity approaches their thermal velocity and hot carrier effects become important. In particular, in Si and Ge, the high field mobility (limited mainly by inelastic phonon scattering) eventually decreases linearly with the electric field and the drift velocity saturates to values close to 10^7 cm/s at electric fields of the order of 10 kV/cm. In the presence of hot carriers, the equivalent valleys need not be equally populated and, as a consequence, even in a cubic material like n-type Ge, the current need not be parallel to the electric field. Moreover, also inequivalent, higher energy valleys may become populated: for instance, dramatic changes in the Hall coefficient of n-type Ge at electric fields higher than 1 kV/cm are brought about by the transfer of electrons from the $\langle 111 \rangle$ lowest minima to the $\langle 100 \rangle$ higher minima, the Hall coefficient is dominated by the contribution of the $\langle 111 \rangle$ high mobility valleys and starts to increase as their population starts to decrease. In several compound semiconductors such as GaAs, such a carrier transfer to inequivalent valleys is responsible for a decrease of drift velocity leading to negative differential resistance (at a field value of about 3 kV/cm in GaAs, as shown in Fig. 9) and also to peculiar current oscillations (Gunn effect) at microwave frequencies. In the presence of hot holes, complex features of the degenerate valence band become important, such as the non-parabolicity of the hole dispersion, i.e., the variation with kinetic energy of the effective mass.

Finally, increasing the electric field strength beyond the saturation regime, a sudden “run-away” growth of the conductivity is eventually observed (breakdown). This is due to the avalanche multiplication of the number of free carriers: the field is so strong

Fig. 9 Temperature dependence of conductivity in Si at various doping levels. From Morin EJ and Maita JP (1954) *Physics Review* 94: 1525.

that a carrier can gain between two collisions enough kinetic energy to knock out an electron from the valence to the conduction band. Typical breakdown electric fields are 10^5 V/cm for Ge, $3 \cdot 10^5$ V/cm for Si and $4 \cdot 10^5$ V/cm for GaAs.

Electron-hole complexes

The discussion above neglects interactions among the free carriers, electrons in the conduction band and/or holes in the valence band. However, when a semiconductor is optically excited at low temperatures it is possible to generate an electron-hole pair absorbing a photon with an energy less than the corresponding interband gap because the electron and the hole attract each other and can form bound states known as excitons. In typical inorganic semiconductors, due to large dielectric constants and small effective masses, such bound states have a large radius (much larger than the lattice constant) and small binding energies (of order 10 meV). Electron-hole complexes larger than excitons also occur, such as biexcitons corresponding to a bound pair of excitons. In the presence of an excess of free carriers, charged electron-hole complexes can also form, the simplest case being that of trions: an exciton bound to either an electron (negative trion) or a hole (positive trion). At high excitation densities, excitons unbind giving way to an electron-hole plasma.

Conclusion

The paramount role of semiconductors in the electronic industry is mainly due to the possibility of suitably controlling their electronic properties via intentional doping. The features of their electron and hole pockets, and in particular the effective masses, affect their functional behavior. We have reviewed the main aspects of the physics of free carriers in semiconductors focusing on transport properties (conductivity and mobility, cyclotron resonance, Hall effect) and their dependence on doping levels and temperature.

Abstract

Electron–phonon coupling is discussed in the context of nanostructures and low-dimensional materials from a theoretical and modeling perspective. After a short review of historical models and modern first-principles techniques, we focus on the effects of nanostructuring and dimensionality. Various mechanisms are considered, from modifications of the joint density of states and energy selection rules, to the emergence of intrinsically different types of electron–phonon coupling in low-dimensional materials. Finally, key issues and perspectives for the future of the field are discussed.

Key points

- Theory of electron–phonon coupling and polarons in condensed matter
- Changes in low-dimensional systems 0D, 1D, 2D
- Polaronic effects

Introduction

The interaction between electrons and atomic vibrations is central to many phenomena in condensed matter physics. Electrons are the main active particle in matter, carrying electrical charge, creating chemical bonds, and interacting with light, magnetization, and other degrees of freedom; vibrations, quantized as phonons, are the lowest energy excitations universally present in any condensed matter systems—metallic or insulating, magnetic or not.

The combination of a charge carrier with the perturbation of the lattice it may induce is called a polaron. This hybrid quasi-particle is a bound state, as it lowers the system's energy. It is characterized by a shift of the associated electron and phonon energies, and, for sufficiently strong coupling, by a net shift of the atoms' equilibrium positions.

One of the most spectacular macroscopic consequences of the coupling between electrons and vibrations (electron–phonon coupling—EPC) is conventional superconductivity, where the vibrational interaction allows electrons to assemble in Cooper pairs, which can condense at low temperature into a quantum state with no electrical resistance (Bennemann, 2023; Chubukov, 2023). Recent progress in 2020 has even shown conventional superconductivity above ambient temperature, by applying extremely high pressures to hydrogen-rich alloys (Shimizu, 2023).

In the normal (nonsuperconducting) state, phonons interfere with the conduction of electrons, and explain the change of the electrical resistivity with temperature in metals, or of the mobility in doped semiconductors. Thermoelectric transport translates a temperature gradient into an open-circuit electrical potential difference (Seebeck effect), and is a direct combination of the electron dispersion relations (energies and group velocities) with the limitation of the electron mean free path by interaction with phonons. At low temperatures, the effect can even be enhanced by phonon drag, where a phonon heat current transfers momentum to the electrons, boosting the Seebeck coefficient.

Structural distortions coupled to electronic reorganization also explain the closely related phenomena of charge density waves, and Peierls and Jahn–Teller instabilities. By condensing a phonon mode displacement, the system gains electronic energy at the expense of elastic deformation, with a net stabilization at low temperature, often accompanied by a metal to insulator transition.

At the nanoscale, electron transport through individual molecules is very sensitive to the energy of the electrons. Inelastic electron tunnelling spectroscopy measures a current from an atomically sharp tip into a molecule, and is sensitive not only to the discrete electronic states of the molecule but also to vibrational sidebands, where an electron hops on to or off of the molecule either emitting or absorbing a vibrational quantum. By scanning the bias voltage of the tip, current peaks are observed in resonance with the molecular electronic levels, plus additional peaks offset by the vibrational frequencies. More generally, many spectroscopic experiments present phonon-dependent features such as peak broadenings and/or the appearance of satellite peaks, offset by the energy of the corresponding phonon mode, and with an intensity governed by the electron–phonon interaction.

The EPC enters many physical observables (transport, superconductivity, etc.), but in an averaged way: summing over the interactions of all phonons with all electrons. The most interesting probes of EPC are microscopic, resolved in electron and/or phonon states. One of the most powerful is angle resolved photo-emission spectroscopy (ARPES), which measures the electron spectral function, that is, a momentum-resolved generalization of the density of states. Phonon renormalization induces a shift and broadening of the original electron bands, kinks where the electron and phonon dispersions cross, and satellite replica, as shown in Fig. 1 for a 2D bilayer of BN and graphene (Chen et al., 2018). The BN valence band presents replica images lowered by one or two vibrational quanta. In these nanostructured interfaces the vibrations are characteristic of the combined bilayer system.

Another example of rather direct and nanoscale access to the EPC is the diffusion of alpha particles off of solid surfaces, which allows to determine the dispersion of surface phonons. The diffusion probability is proportional to the electron–phonon coupling, as the He interacts mainly with the electron cloud, which then launches the phonons (Campi et al., 2015). This is shown in Fig. 2 for a surface of xenon.

In this chapter, we present the current state-of-the-art of the phenomenology and theory of electron–phonon coupling, with a specific focus on the effects of nanostructuring and dimensionality in ultrathin layers (2D), wires or tubes (1D), and nanoparticles (0D). We finish by presenting open issues of debate and future perspectives in the field.

Overview

In this section we survey the main theoretical and modeling approaches used for the coupling of electrons and phonons, their consequences for transport, spectroscopy and other observables, and how these change in lower dimensions. The interaction of an electron (or hole) with ambient phonons lowers the total energy, producing a combined bound state known as a polaron. Here we will concentrate on the electron–phonon coupling itself, and first-principles formalisms calculate EPC and derived observable quantities, and in particular on the effects of dimensionality. We will mainly treat semiconducting and insulating materials, though most expressions hold for metals as well.

Historical models

Several models have been used in the past to understand polaronic behaviors and EPC. One of the simplest is the Holstein Hamiltonian (Holstein, 1959) involving a single phonon mode, electrons on a tight binding lattice, and a linear, on-site electron

Fig. 1 ARPES bands of h-BN alone (A) and in heterostructure with graphene (B), which shows in (C) polaronic satellite replica of the main BN band, due to phonons hybridized with graphene. phonon coupling term. It is useful for strongly localized carriers and phonons, as in molecular crystals, leading to small polarons and hopping transport.

In the 1D Su Schrieffer Heeger (Su et al., 1979) model the EPC is an inter-site exchange-like term, where the phonon and electron both hop from one site to another. Prototypically in an acetylene chain, alternating bond lengths can be seen as the freezing-in of an atomic vibration, with corresponding localization of an electron in a C = C bond. This gives rise to traveling charged excitations and solitons.

An omnipresent type of EPC involves acoustic phonons at small wavevector. By approximating the acoustic phonon by a homogeneous elastic dilation known as the deformation potential (Bardeen and Shockley, 1950), the resulting change in electron band energies will be linear. This yields a simple Hamiltonian in reciprocal space for a parabolic band and isotropic acoustic phonons.

In band insulators and semiconductors with more than one atomic species, the perturbation of the lattice by optical phonons generates dipoles, and the associated electric fields couple to electrons. This effect is strongest in ionic crystals, and was described by the Fröhlich model (Fröhlich, 1952), used to model large polarons with variable coupling strength. The Hamiltonian is expressed as

$$H^{\text{Fr}} = \sum_k \frac{k^2}{2} \hat{c}_k^\dagger \hat{c}_k + \sum_q \hat{a}_q^\dagger \hat{a}_q + \sum_{k,q} \frac{1}{q} \left(\frac{2\sqrt{2}\pi\alpha}{V} \right)^{\frac{1}{2}} \hat{c}_{k+q}^\dagger \hat{c}_k (\hat{a}_q^\dagger + \hat{a}_{-q}) \quad (1)$$

where k and q are electron and phonon momenta, respectively. This Hamiltonian contains a single dispersionless longitudinal optical (LO) phonon frequency ω_{LO} ($\hat{a}_q$ operators), and a parabolic electron band with effective mass m^* ($\hat{c}$ operators) in a volume V . The coupling is a long-range dipolar interaction between the electron and the macroscopic electric field produced by the LO phonon. The EPC varies with q and depends on a reduced coupling parameter:

$$\alpha = \left(\frac{1}{\epsilon^\infty} - \frac{1}{\epsilon_0} \right) \sqrt{\frac{m^*}{2\omega_{\text{LO}}}} \quad (2)$$

mixing the phonon frequency, electron mass, and electronic (ϵ^∞) and static (ϵ_0) dielectric constants, respectively, at large frequency (much higher than the vibrations) and zero frequency. A full solution was found using the path integral method (Feynman, 1955), and more recently using diagrammatic Monte Carlo (Mishchenko et al., 2000).

The models presented each focus on a specific type of EPC and require measurements or choices for the parameters. A more systematic and quantitatively predictive approach arises from first-principles methods (Giustino, 2017).

Microscopic ab initio formalism

The electron-phonon coupling is defined as the quantum probability of interaction between an electron and a phonon. We will mainly consider the case of ideal periodic crystalline solids, and associate a wavevector, band index, and energy for both the electron (k, n) and phonon (q, j). Most of our development is also valid for molecular crystals with more localized electron and phonon states, which then hop between molecules: the main difference is the dispersion relations, the phonon states being fully localized ($q = 0$), and the electron bands being almost dispersionless with high effective mass.

In their ground state without EPC, the electrons occupy eigenstates of the unperturbed Hamiltonian, for atoms in their equilibrium high-symmetry positions. A displacement of the atoms collectively following a vibrational normal mode will produce a change δV in the potential felt by the electrons. If this change is small, to first order the probability amplitude of scattering an electron is given by

$$g_{nm\vec{k}}^{\vec{q}j} = \langle \psi_{\vec{k}+\vec{q}m} | \delta V^{\vec{q}j} | \psi_{\vec{k}n} \rangle \quad (3)$$

where the final state must conserve energy ($\epsilon_{\vec{k}+\vec{q}m} = \epsilon_{\vec{k}n} + \hbar\omega_{\vec{q}j}$) and momentum (final state at $\vec{k} + \vec{q}$). Within many-body perturbation theory (MBPT), the effect of the phonons on the electrons can be included via a self-energy: an effective energy-dependent potential which translates the consequences of interactions on the “bare” independent carriers. To first order in phonons (Migdal, 1958 showed that this approximation is a very good one) there are two pieces of the EPC self-energy, the so-called Fan and Debye–Waller terms. The former is energy dependent and corresponds to the emission and later re-absorption of a phonon:

$$\Sigma_{nk}^{\text{FAN}}(\omega) = \frac{1}{N_q} \sum_{mj\vec{q}} |g_{nm\vec{k}}^{\vec{q}j}|^2 \left(\frac{n_{j\vec{q}}(T) + f_{m\vec{k}+\vec{q}}(T)}{\omega - \epsilon_{m\vec{k}+\vec{q}} + \omega_{j\vec{q}} + i\eta} + \frac{n_{j\vec{q}}(T) + 1 - f_{m\vec{k}+\vec{q}}(T)}{\omega - \epsilon_{m\vec{k}+\vec{q}} - \omega_{j\vec{q}} + i\eta} \right) \quad (4)$$

The latter is instantaneous and energy independent, corresponding to the phonon-induced creation of virtual electron–hole pairs. Within a rigid ion approximation, it can be rewritten in a form similar to the Fan term. The importance of retaining both terms was recognized after much debate in the 1960s and 1970s. A synthesis was realized by Allen, Heine, and Cardona (Allen and Heine, 1976), to calculate the renormalization of the optical band gap at $T = 0$ K, and its evolution with temperature.

In practice the ingredients (electron and phonon states and coupling matrix elements) are most often calculated within density functional theory (DFT, Nomura and Akashi, 2023) and the corresponding perturbation theory (DFPT). We will not go into any detail about DFT theory: the coupling matrix elements can be evaluated explicitly within DFPT, then summed with the expressions above, or included implicitly through a configuration average over thermally populated configurations in a “supercell” approach. In the latter case, specific observables (dielectric function, band structure and gap, etc.) are evaluated and averaged for many disordered configurations sampling a canonical average. However this approach is static and adiabatic, and some limitations are discussed below. The historical Fröhlich model can be advantageously leveraged to make ab initio computations more accurate and tractable. In 2015, several groups (Sjakste et al., 2015; Verdi and Giustino, 2015) combined Fröhlich with first principles calculations of EPC. In three dimensions and for polar materials, the EPC matrix elements diverge for vanishing phonon momenta at the Brillouin zone center (usually as $1/q$, but not always, see Poncé et al., 2015), which bedevils numerical convergence. This divergence is treated by subtracting an analytical Fröhlich EPC interaction, then later adding it back. This amounts to separating long-ranged (small q) dipolar interactions from the other short-ranged, better-behaved interactions. Many quantities depend on reciprocal space integrations which can be performed accurately only with this technique. Phenomena such as ferroelectricity and piezoelectricity can be addressed quantitatively. In 2020 the same principle was carried over to quadrupole effects (Brunin et al., 2020; Jhalani et al., 2020). The quadrupole EPC does not diverge, but it does present discontinuities and a nonanalytic behavior around the Brillouin zone center.

Combining recent progress on low-dimensional materials and hindsight on decades of research into nanostructured systems, one may distinguish two types of dimensionality effects on electron–phonon interactions: (i) discretization of the electron and/or phonon bulk states and (ii) new phonons and couplings. These are discussed in the following sections.

Discretization of the electron and/or phonon bulk states

By reducing the dimensions in which electrons and phonons can propagate, one affects first and foremost their density of states. Confining boundary conditions on the electron’s wavefunctions or the phonon’s displacement pattern impose discrete values for the momenta in the confined directions. This is reflected in the density of states (DOS) of the free electron gas, which goes from a continuous square root of the energy in 3D to a discontinuous function with repeating features in lower dimensions, coming from the discrete values of the confined momenta: steps in 2D, inverse square roots in 1D, and Dirac peaks in 0D. Because of the conservation of energy and momentum, this will immediately affect the selection rules involved in electron–phonon interactions (Ridley, 1982), and the consequences have been observed in quantum wells, wires, and dots for several decades. The joint density of states represents the statistical availability of each quasiparticle, as well as the energy and momentum selection rules involved in the transitions. When the joint density of states is large, both electrons and phonons have many options to scatter, leading to short scattering times (average time between two scattering events) and a broadening of their respective spectra, whose width goes as the inverse of the scattering time (e.g., Lazzeri et al., 2006). As dimensionality is reduced, so is the joint density of states, and the scattering time associated with each quasi particle is generally expected to increase, for example, for the phonon bottleneck effect in quantum dots (Inoshita and Sakaki, 1996). On the other hand, one may also observe hybrid quasi-particles (polarons) at specific resonance conditions between electron and phonon energies. Standard realizations are quantum wells in a magnetic field, with 0D electron states which are tunable via the cyclotron frequency (Klimin and Devreese, 2003), or quantum dots with electron energy spacings corresponding to LO phonon energies (Hameau et al., 1999).

Fig. 3 DFPT simulation of polar-optical phonons in BN and MoS₂. Dimensionality affects the dispersion of polar-optical phonons, as well as their coupling to electrons. The frequency shift associated to dipolar interactions is constant in 3D, while it breaks down at zone center ($q \rightarrow 0$) in 2D, as seen on the left panel for BN. The Fröhlich electron–phonon coupling with the LO phonons diverges as the inverse of the phonon momentum in 3D (bulk MoS₂), while it stays finite in 2D (monolayer MoS₂) at zone center. Adapted from Sohler T, Calandra M, Mauri F, 2016. Two dimensional Fröhlich interaction in transition-metal dichalcogenide monolayers: theoretical modeling and first-principles calculations. *Physical Review B* 94 (8), 085415. ISSN 2469-9950. <https://doi.org/10.1103/PhysRevB.94.085415>; Sohler T, Gibertini M, Calandra M, Mauri F, Marzari N, 2017b. Breakdown of optical phonons’ splitting in two-dimensional materials. *Nano Letters* 17 (6), 3758–3763. ISSN 15306992. <https://doi.org/10.1021/acs.nanolett.7b01090>. 1612.07191.

The reduction of dimensionality will change the dielectric screening, as well as the dispersion of the polar (Fröhlich-type) EPC, as shown in Fig. 3. With reduced screening and stronger interactions, the formation of bipolarons (bound states composed of two polarons) is also easier in lower dimensions. Depending on the mechanical and electrical boundary conditions, with a surface or embedding in a matrix, one can also be in mixed dimensions, for example, 2D electrons interacting with 3D phonons. Extensive work was carried out in the 1990s and 2000s linking polarons, dimensionality, and superconductivity in 2D gases and cuprates (Alexandrov and Devreese, 2010).

New phonons and couplings

We now focus on the second category of dimensionality effects: the emergence of new phonons and couplings. Relatively large nanostructures can be approximated as containing a combination of bulk and surface states. Nanostructuring a bulk 3D material creates boundaries and generates phonon and electron states that are different from the bulk. At the interface between two materials (or a material and vacuum), electronic surface states are formed as the potential transitions sharply to that of the other medium (Chiarotti and Goletti, 2005). Several types of surface phonons can emerge. Some have frequencies well separated from the bulk dispersion, clearly implying surface localization (see mode S1 in Fig. 2). Other “embedded surface modes” have frequencies within the bulk phonon bands, yet are still localized on the surface, which induces resonances in the bulk spectrum (Benedek et al., 2020). Due to their spatial localization, such surface electron and phonon states couple mostly to each other, with a limited joint density of states. The resulting states can be observed with experimental surface techniques such as ARPES (Hofmann et al., 2009).

Smaller nanostructures or low-dimensional materials, on the other hand, may lose more of their similarity with the bulk. Any phonon with atomic displacements in directions which are not periodic will necessarily differ strongly from the bulk modes.

This is clear for phonons with out-of-plane atomic displacements in 2D materials. The acoustic out-of-plane mode (ZA) follows a distinctive quadratic dispersion, leading to much smaller energy and larger occupations at small finite momenta than in 3D. The optical out-of-plane mode (ZO) is typically less energetic than its in-plane counterparts as well. Both do not couple to electrons at linear order unless mirror symmetry is broken by the material itself (Zhang et al., 2021) or by an external electric field, as suggested notably for graphene (Gunst et al., 2017; Politano et al., 2015; Sohler et al., 2017a). Similar conclusions apply to phonons with displacements perpendicular to the periodic direction in 1D systems like nanotubes, chains, or thin nanowires.

Phonons with atomic displacements in the bulk-like direction may also change with nanostructuring. This is the case of polar-optical phonons, and the contribution of dipolar interactions to the energy of longitudinal optical (LO) modes. If there exist transverse phonon modes (TO) which are degenerate in the absence of the long range electrostatic interaction, this leads to the so-called LO/TO splitting (hardening of the LO mode). The dimensionality of the sample leads to different dispersions for the phonons near the Brillouin zone center. Notably in 2D the LO/TO splitting vanishes in the very long wavelength limit (De Luca et al., 2020) and has a linear increase at small q (Sohler et al., 2017b), see Fig. 3. The dispersion is also affected by the screening of the dipolar interactions, which depends on dimension. The dielectric function of 2D materials is characterized by a crossover between screening by the environment at long wavelengths, to screening from the layer itself at shorter wavelengths (Royo and Stengel, 2021).

The LO/TO splitting is a field-mediated mechanism, and, for the same reasons, field-mediated electron–phonon coupling in general will be affected by dimensionality. This is the case of the Fröhlich coupling with LO modes, and the piezoelectric coupling with transverse and longitudinal acoustic phonons (TA/LA). The Fröhlich coupling with polar-optical phonons results from the above-mentioned dipoles (and higher multipoles) which are formed when moving atoms with different charges. Piezoelectricity denotes the capacity of certain materials to generate an electric field under strain. Long wavelength TA and LA phonons can be considered as a periodic strain, so in piezoelectric materials a periodic electric field is generated. Dimensionality affects the charge

Fig. 4 Ab initio-based semi-analytical model of remote polar-optical phonon coupling in the van der Waals heterostructure depicted at the top where the number of BN layers (N) is increased from 1 to 4. The curves show the coupling between transport electrons in GaSe and the LO phonons of either GaSe or BN. All the couplings are screened remotely by the doped graphene, but the effect fades as N increases, leading to an increase of the couplings, and lower mobility. The couplings due to BN phonons increase more dramatically as the dielectric contributions from each layer add up. Adapted from Sohier T, Gibertini M, Verstraete MJ, 2021. Remote free-carrier screening to boost the mobility of Fröhlich-limited two-dimensional semiconductors. *Physical Review Materials* 5 (2), 024004. ISSN 2475-9953. <https://doi.org/10.1103/PhysRevMaterials.5.024004> (2011.04961).

density perturbations as well as their screening. The Fröhlich coupling as a function of momentum diverges at zone center in 3D, while it stays finite in 2D (Sohier et al., 2016), as shown in Fig. 3. A similar dependency on the dimensionality is expected for the piezoelectric coupling, as seen by comparing 3D (Jhalani et al., 2020) and 2D models (Kaasbjerg et al., 2013).

Finally, the juxtaposition of low-dimensional systems along their nonperiodic directions leads to the emergence of remote interactions between electrons and phonons belonging to different nanostructures. This is particularly true for field-mediated couplings since the electric fields generated are long range. The remote couplings to different flavors of polar-optical phonons are now understood in several situations. They can in general be modeled by simple electrostatics and dielectric models. The first and now well-known instance of such a mechanism is the coupling to surface optical phonons (Wang and Mahan, 1972). These appear at the surface of supporting substrates, their energy is somewhere between the TO and LO modes of the bulk, and they will generically scatter electrons in whatever system is on the substrate (Fischetti et al., 2001). In van der Waals heterostructures, the relevant modes are the LO phonons of the different layers, which scatter electrons in surrounding layers (Sohier et al., 2021), as shown in Fig. 4. In both cases, the nature of the phonon and the coupling mechanism are very similar. The generated electric field, and thus the associated coupling, is damped as e^{-qd} where q is the phonon momentum and d is the distance between the locations of the phonon and the electrons. Other phonons may couple to electrons remotely, such as acoustic phonons via the piezoelectric coupling or ZO phonons. Ab initio methods have evolved and adapted to simulate dimensionality effects in EPCs. A central challenge is that plane wave codes (those most commonly used to access EPCs) rely on 3D periodic boundary conditions. Nanostructures or low-dimensional systems are thus repeated artificially in the nonperiodic dimension. Certain perturbations, and phonons in particular, lead to long-range interactions in the response of the system. The periodic images can then interact with each other, changing the behavior of the electron–phonon coupling. Truncation techniques have been developed to overcome those issues, and one can now perform phonon and electron–phonon calculations in 2D with the proper boundary conditions (Sohier et al., 2017a). 2D material EPCs are then readily accessible. Surface electron–phonon interaction requires other methodological efforts, using slabs or Green’s functions (Hofmann et al., 2009), which have been resolved well before the periodic image interactions. Remote phonons are accessible in those frameworks, but new technical issues arise, such as the need for large supercells to accommodate the mismatch in different materials’ lattices. Semi-numerical methods have been developed to tackle this issue (Sohier et al., 2021).

Key issues (current debates regarding the topic)

As shown above, electronic screening is an essential ingredient of electron–phonon interactions. It is also a complex quantity to simulate from first-principles calculations. The vast majority of calculations to date are based on DFT, with semi-local exchange-

correlation functionals (local or generalized gradient approximations). A few studies have used hybrid functionals (with a fraction of exact Hartree–Fock exchange) or the GW approximation, for example, in graphene (Lazzeri et al., 2008) and diamond (Antonius et al., 2014). Both treatments tend to open the band gap, lower screening, and increase the EPC. There is not yet a clear consensus about a recipe for the use of higher order methods in the dielectric screening: many purely DFT calculations are quantitatively within experimental error bars for mobility, zero point renormalization, or superconductivity. However, given the complexity of advanced calculations and many possible missing effects (defects and dislocations, anharmonicity, boundary scattering) there will be a systematic need for better screening to push accuracy further.

Consistent treatment of EPC within many-body theory implies that the interaction vertex (essentially the EPC matrix element) should appear once screened and once “unscreened” in the self-energy (Calandra et al., 2010; Giustino, 2017), as is also the case for electron–electron interactions. Most practical calculations use matrix elements from DFPT, screened by the DFT dielectric response, in all of the self-energy insertions. This has led to an extensive and not yet fully resolved debate about the importance of the approximation involved in screening all vertices the same way, and the proper way to unscreen or rescreen DFPT results.

A crucial consideration in all perturbation theories is the separation of energy scales. Neglecting the energy of a phonon before that of an electron yields an effectively adiabatic interaction, continuously following a single potential energy surface for the electrons. In explicit expressions, such as the Fan self-energy above, the phonon frequency can be included (or not) in energy denominators, leading to a direct test of the consequences of nonadiabaticity. Techniques averaging supercell properties are always implicitly adiabatic (static) with respect to the phonon, and it has become clear recently that this is incorrect for certain quantities.

Macroscopic properties of semiconductors are often computed by plugging the neutral EPCs into models for different transport and optical quantities. However, gate doping and optical pumping are ubiquitous in experiments on nanostructures, implying that the carrier occupations are not those of the neutral material. Instead, extra electrons and/or holes are created. This changes the EPCs, the most obvious consequence being the screening of the EPCs by the added free carriers, generally corresponding to a suppression of the couplings with doping. Thus, in principle, the EPC matrix elements should be computed with the nonequilibrium, nonneutral occupations. Semi-numerical models have been developed to correct the EPCs of neutral semiconductors (Gjerding et al., 2020; Verdi et al., 2017). Those models allowed, for example, to understand the transition between polaronic and Fermi liquid states observed in the ARPES spectra of transition metal oxides (Verdi et al., 2017). A more systematic *ab initio* treatment of doped semiconductors has recently been proposed in 3D semiconductors (Macheda et al., 2022), and the EPCs of gate-doped 2D semiconductors have become accessible directly within DFPT (Sohier et al., 2017a).

The simplest models of EPC consider a single valley at the band edge. Multivalley band structures, however, complicate this picture. Beyond the emergence of intervalley scattering, the intravalley EPC of 2D transition metal dichalcogenides (TMDs) has been shown to be enhanced when two kinds of valleys are occupied (Sohier et al., 2019b). The coupling can be described by a “multivalley” deformation potential that has the peculiarity of perturbing the different valleys of the conduction band with opposite phase, which leads to vanishing screening and a counterintuitive enhancement of the EPC with doping.

The detailed study of transport and optical properties of TMDs has revealed the importance of the interplay between electron–phonon scattering and spin-orbit coupling. Electron–phonon interactions are mostly spin-conserving, implying that the spin texture of a band structure will dictate which electronic states can be coupled via phonons. This has clear consequences on excitonics and carrier relaxation in general, which should be systematically accounted for.

The standard flavors of EPCs were identified in the 1950s with the deformation potential (Bardeen and Shockley, 1950), and the Fröhlich interaction (Fröhlich, 1952). There are other kinds of couplings. The piezoelectric interaction coming from acoustic phonons (Jhalani et al., 2020) is generally weaker and vanishes at small momenta, and it has been studied somewhat less intensely than the (also field-mediated) Fröhlich coupling with optical phonons, in particular with respect to nanostructuring and dimensionality effects. The deformation potential formalism was initially formulated in the framework of acoustic phonons, describing an energy shift of the band edge induced by a strain (volume change). It can however be extended to describe a similar energy shift induced by any phonon perturbation, such as optical phonons. Another important type of EPC that was particularly studied in graphene is the so-called “gauge-field.” Intuitively, it can be understood as producing a shift in momentum of the valleys (rather than energy), as the atoms follow the phonon displacement pattern. It has the peculiarity of being insensitive to screening, and so it is robust with respect to a change in the dielectric environment or doping. Finally, intervalley EPCs, that is, large momenta phonons coupling electronic states in different valleys, can play a significant role in electron relaxation (Sohier et al., 2019a).

All the “nonstandard” flavors of EPCs are straightforwardly accessible within DFPT. EPC models limited to the deformation potential are still widely used to estimate transport properties, although with very limited accuracy in certain situations. A clear understanding of the nature of the different kinds of couplings is crucial for EPCs in nanostructures.

Conclusion

Summary

The coupling of electrons and phonons has made immense progress in the past half century. In particular the incorporation of first-principles electronic structure ingredients has made quantitative predictions possible and led to a resurgence of the field since the 2000s, with applications to polarons, mobility and transport, and phase transitions and spectroscopy. This chapter presents the current state of the art in the calculation of EPC and derived quantities, with a specific focus on the effects of dimensionality and nanostructuring. Geometric quantum confinement changes the density of states of both electrons and phonons, though not

necessarily to the same extent, for example, for electrons in quantum dots embedded in the lattice vibrations of a matrix. Further, the phonons themselves and the mechanisms by which they couple to electrons are affected by dimensionality. For example, the dielectric screening is less efficient in lower dimensions, which qualitatively changes the Coulomb interaction and long wavelength phonon dispersion.

Different types of phonons lead to different couplings. Traditional focus on acoustic modes (deformation potential) and longitudinal optical modes (Fröhlich) has now broadened into a rich variety of behaviors including piezoelectric, gage field, and multivalley deformation potentials, and even “nonpolarons” (de Abreu et al., 2022; Emin and Bussac, 1994).

Future directions

The exploration of novel types of couplings as well as their myriad consequences on physical observables is a very active field of research. We list below some promising directions for future investigation. The community has begun addressing a systematic combination of different interactions within many-body perturbation theory. In this light electron–electron, electron–phonon, and phonon–phonon interactions should all be included, though they can present very different energy scales and intensities. A first step is the renormalization of the ingredients for EPC calculations, for example, using the GW approximation to improve the electronic band energies, or using self-consistent harmonic approximations to improve the temperature dependency of the phonons, and then combining these with the $T = 0$ DFPT EPC. First attempts at a fuller theory have been proposed within MBPT, as the addition of the e–e and e–ph self-energies to correct the noninteracting electron Green’s function. More broadly, extensive effort is being invested in the interaction between phonons and other quasiparticle excitations such as excitons (electron–hole pairs) and polaritons (electron–photon or phonon–photon hybridization).

The explicit representation of polarons remains an active challenge: wavefunction Ansätze were usually restricted to Gaussian functions with a single variational parameter in their width. Using first-principles ingredients, more evolved polaron wavefunctions can be constructed as recently shown by Sio et al. (2019). Bridging the gap between small and large polaron scales, and weak to strong coupling with a unique formalism is still a distant perspective. Many-body approaches based on perturbation theory can manage relatively strong couplings but still break down in nonrenormalizable cases such as small localized polarons. The interplay between polaron strength, localization, and dimensionality will be a further challenge.

Ultrafast real time dynamics of electron and phonon populations have been demonstrated using the ingredients described above (Caruso, 2021; Tong and Bernardi, 2021). A fully nonequilibrium theory, where the EPC itself evolves in time, will be the next frontier, linked to the many-body considerations above.

Beyond optical properties, polaronic effects may also impact transport in materials with relatively strong electron–phonon couplings. A cumulant approach was used to renormalize the electron–phonon self-energy (Story et al., 2014), and more recently applied to model spectroscopy and transport in this regime, paving the way for further study of the electrical characterization of polaronic effects.

While EPCs in standalone 2D materials have already raised considerable interest, there is still much to understand about EPCs in twisted heterostructures of 2D systems. As found in twisted bilayer graphene, both electron and phonon states can be dramatically affected by the Moiré pattern created when aligning lattices at different angles. Significant consequences on EPCs naturally emerge as well (Choi and Choi, 2021), and their understanding will surely shed light on the many experiments conducted on this kind of 2D systems.

Finally, as the energy and momentum resolution of experimental techniques progress, various pathways to measure EPCs are now available. Over the last decade there have been spectacular improvements in neutron scattering, nonresonant inelastic X-ray scattering and Raman spectroscopy to probe EPCs via phonons, and ARPES to probe EPCs via electrons. Recent progress in the postprocessing of techniques like resonant inelastic X-ray scattering (Dashwood et al., 2021; Devereaux et al., 2016) or time-resolved ARPES (De Giovannini et al., 2020; Hein et al., 2020) have allowed a more direct, momentum- and mode-resolved access to EPCs.

This progress heralds an exciting back and forth between experiments and theory, as experiments zero in on the measurement of specific electron–phonon coupling matrix elements, rather than averaged macroscopic quantities.

Abstract

An overview of the electronic band structures of elemental semiconductors is presented, emphasizing the role of symmetry in determining their qualitative aspects. Their relation to the optical spectra and photoemission data is discussed. Besides Si and Ge, which have an indirect gap, a few other examples of semiconductors with a “zero-gap” or a direct gap are illustrated.

Introduction

Silicon, the paradigmatic elemental semiconductor, is by far the most relevant material in the electronic industry and possibly the best known solid both from the point of view of basic science and technology. Our present understanding of virtually all the properties of a crystalline solid such as Si is based on an accurate knowledge of its electronic states, i.e., its electronic band structure. Quantum mechanics predicts the energies and wavefunctions available to the electrons in the periodic crystal potential (Bassani and Pastori Parravicini, 1975). Differently from the case of atoms or molecules, the translational symmetry of the crystal leads to extended states characterized by a Bloch wave-vector k . Just like in atoms and molecules, the Pauli exclusion principle dictates how the distinct electronic states are occupied each by a single electron starting from the lowest energy levels. From such information, mechanical, transport and optical properties can be inferred (Bassani and Pastori Parravicini, 1975; Cohen and Chelikowsky, 1988; Yu and Cardona, 1995).

Semiconductors have typically an energy gap (E_g) between the highest occupied states (top of the valence band) and the lowest unoccupied ones (bottom of the conduction band) comparable to 1 eV and are characterized by the possibility to be doped. Silicon ($E_g = 1.17$ eV) and germanium ($E_g = 0.774$ eV) are the most important elemental semiconductors, belong to group IV of the periodic table, are tetrahedrally coordinated and crystallize in the diamond structure with cubic symmetry. We will focus here on Si and Ge, which have an indirect gap, and to a lesser extent on grey tin (α -Sn, a “zero-gap semiconductor”), black phosphorous and hexagonal germanium, both of which have a direct gap.

The main features of the electronic bands are determined by the symmetry of the crystal more than by the detailed shape of the crystal potential, and there are strong similarities in the band structures of Si, Ge and α -Sn, which have the diamond crystal structure. In the following, we will first describe the symmetry properties of the diamond crystal and the main ingredients to calculate the energy bands, then the electronic band structures of Si, Ge and α -Sn and their direct comparison with optical and photoemission experiments. Finally, we will consider two elemental semiconductors, hexagonal germanium and black phosphorous, which have a different crystal structure and are of interest for light-emitting applications.

Crystal structure and symmetry

The group IV elemental semiconductors, like carbon, are characterized by four electrons in the outer shell, with an electronic configuration $s^2 p^2$ which in the solid gives rise to four tetrahedrally oriented sp^3 hybrid orbitals. The resulting network of covalently bonded atoms corresponds to a face-centered cubic crystal in which each atom occupies an equivalent position. Such diamond crystal belongs to the $Fd\bar{3}m$ (O_h) crystallographic space group having the point group full cubic symmetry O_h .

Its translational symmetry is described by a Bravais FCC lattice of primitive translations: $\vec{\tau}_1 = (a/2)(0, 1, 1)$, $\vec{\tau}_2 = (a/2)(1, 0, 1)$ and $\vec{\tau}_3 = (a/2)(1, 1, 0)$, where a is the side of the conventional unit cell, i.e., the crystal is invariant for translations by any vector $\vec{R} = n_1 \vec{\tau}_1 + n_2 \vec{\tau}_2 + n_3 \vec{\tau}_3$, with integral values of n_1 , n_2 and n_3 . The lattice constants of cubic elemental semiconductors are $a = 5.43 \text{ \AA}$ for Si, $a = 5.65 \text{ \AA}$ for Ge, $a = 6.46 \text{ \AA}$ for α -Sn. The corresponding reciprocal lattice is body-centered cubic (BCC) with primitive vectors: $\vec{K}_1 = (2\pi/a)(\bar{1}, 1, 1)$, $\vec{K}_2 = (2\pi/a)(1, \bar{1}, 1)$ and $\vec{K}_3 = (2\pi/a)(1, 1, \bar{1})$; there-ciprocal lattice vectors, $\vec{G} (\vec{G} = m_1 \vec{K}_1 + m_2 \vec{K}_2 + m_3 \vec{K}_3)$, with m_1 , m_2 and m_3 integers, have the property: $e^{i\vec{R}\cdot\vec{G}} = 1$, for any lattice translation $\vec{R}$. The primitive (symmetric) cell of the reciprocal lattice, i.e., the first Brillouin zone (BZ), of the diamond structure is shown in Fig. 1. The physical significance of the reciprocal lattice and of the BZ is that, as a consequence of the periodic translational symmetry, the extended electronic states in a crystal are described by wavefunctions of the form $\Psi_{\vec{k}}(\vec{r}) = e^{i\vec{k}\cdot\vec{r}} u(\vec{r})$ (Bloch's theorem), where the wavevector $\vec{k}$ belongs to the BZ and the function u is invariant under lattice translations ($u(\vec{r} + \vec{R}) = u(\vec{r})$).

Beside the FCC lattice translations, the rotations and reflections belonging to the full cubic group (O_h) leave the diamond structure invariant. At the microscopic level, though, half of the 48 symmetry operations of O_h are accompanied by a fractional translation such that the two interpenetrating fcc lattices are exchanged (the space-group of diamond being a non-symmorphic space-group with a basis of two atoms). This is the main difference with respect to the zinc-blend symmetry of compound semiconductors such as GaAs in which the two sublattices are not equivalent. In particular, an elemental semiconductor such as Si has inversion symmetry with respect to the middle point of its homonuclear covalent bond, whereas in a compound semiconductor such as GaAs this symmetry is lacking. The point-group symmetry determines the degeneracies of the electronic levels as a function of their wavevector $\vec{k}$ in the BZ zone. In particular, the electronic wavefunctions at points and lines of high symmetry in the BZ, those marked in Fig. 1, are characterized by their transformation properties under point-group symmetry operations that leave their wavevector unchanged (i.e., they belong to the irreducible representations of the little group of their wavevector).

Beside space-group symmetry, time-reversal symmetry also affects the properties of a crystal, and it may bring about additional degeneracies of the electronic states. In particular, when the spin of the electrons is taken into account, in a crystal with inversion symmetry (such as Si) at each wavevector $\vec{k}$ the electronic states are (at least) doubly degenerate, because the state $|\vec{k}, \uparrow\rangle$ with spin up is degenerate with the state $|\vec{k}, \downarrow\rangle$ by inversion symmetry and the latter is degenerate with the state $|\vec{k}, \uparrow\rangle$ by time-reversal symmetry. The spin degeneracy between the states $|\vec{k}, \uparrow\rangle$ and $|\vec{k}, \downarrow\rangle$ is, in general, absent in materials lacking an inversion center (such as in GaAs). Standard group theoretical methods are employed to obtain systematically all the wealth of information that symmetry alone provides.

Energy band calculations

Even though translational symmetry enormously simplifies the computation of the electronic states in a crystal, reducing the size of the problem to that of a unit cell, still a quantitative band structure calculation usually adopts a number of approximations. The electrons are considered to move in the presence of nuclei fixed at the equilibrium positions of the lattice (adiabatic

Fig. 1 Brillouin zone of the diamond crystal; lines and points of high symmetry are indicated.

approximation). The electron-electron interactions are treated at the mean field level neglecting many body correlations (one particle approximation). Finally, the interactions with the nuclei, including typically also the core of inner electronic shells, and with all other electrons in average are lumped into a local potential $V(\vec{r})$ which has the full symmetry of the crystal (band approximation). The crystal potential $V(\vec{r})$ can be either chosen empirically or determined within a self-consistent *ab initio* scheme. The solution of the corresponding Schrödinger equation for the electronic states

$$\left[\frac{p^2}{2m} + V(\vec{r}) \right] \Psi_{n,\vec{k}}(\vec{r}) = E_n(\vec{k}) \Psi_{n,\vec{k}}(\vec{r}),$$

gives the (possibly degenerate) Bloch eigenfunctions Ψ with a wavevector $\vec{k}$ in the BZ and a band index n , which correspond to the electronic energy levels $E_n(\vec{k})$, i.e., the energy bands which depend continuously on $\vec{k}$. Relativistic corrections can be included in the above equation and may be important for heavy elements as discussed later on.

There are numerous and diverse methods to calculate the energy bands. In particular, some consider a crystal as a collection of atoms (localized orbital methods), while others treat it as a perturbed uniform fluid (plane-wave methods). A very popular localized orbital approach is the tight-binding method in which the wavefunctions are expanded in a basis of linear combination of atomic orbitals (LCAO); usually, only a limited number of atomic orbitals are included and only the interactions among a limited number of neighbors are considered. This method, at least in its simpler semiempirical versions, is transparent and economic; it has been very successful in calculating both electronic and structural properties of semiconductors and establishing their chemical trends. The minimal tight binding model to rationalize the electronic band structure of elemental semiconductors, at least concerning their valence band states, is sketched in Fig. 2. For each one of the two atoms in the elementary unit cell, a basis of atomic states is chosen including only one *s* and one *p* level (respectively, two and six times degenerate including spin). If we imagine to bring two atoms close together as in a diatomic molecule, each level would give rise to one bonding and one antibonding molecular orbital, the former having a lower energy. In the Ge crystal, e.g., such states give rise at the center of the BZ at $\vec{k} = 0$ (the Γ point) to a sequence of levels having the full cubic symmetry and corresponding, in order of increasing energies, to an *s*-bonding-like Γ_1 level, a *p*-bonding-like Γ_{25}' level, an *s*-antibonding-like Γ_2' level and a *p*-antibonding-like Γ_{15} level. The eight outer shell electrons (four for each atom in the unit cell) fill the Γ_1 and Γ_{25}' levels completely, the latter being thus the top of the valence band, while the Γ_2' and Γ_{15} levels remain empty (conduction states). State of the art tight binding calculations, of course, are based on larger basis sets, possibly including also *d* states (Jancu et al., 1998), and can describe well also the more delocalized conduction band states (see Table 1).

Fig. 2 Scheme showing how lower lying bonding (b) and higher lying antibonding (a) molecular levels give rise to Bloch states of specific symmetry at the Γ point in Ge.

Table 1 Energy levels in silicon and germanium in eV, from the top of the valence band; the double-group symmetry labels including parity are indicated.

Fig. 3 Empty lattice band structure for a diamond-like crystal.

The plane-wave based methods take an opposite point of view and start considering the electronic states in the presence of a very small crystal potential: in such “empty lattice” the zeroth order eigenfunctions of nearly free electrons are just plane waves folded back in the BZ according to the translational symmetry as sketched in Fig. 3. For instance, looking again at the Γ point, the lowest energy level corresponds to a plane wave with a vanishing wave vector (Γ_1 state in the cubic crystal), while the next higher level includes the eight plane waves having a wave vector of the form $\vec{q} = (2\pi/a)(\pm 1, \pm 1, \pm 1)$, which differ from zero by one of the shortest non zero reciprocal lattice vectors. When the crystal potential is turned on, these 8 states (16 including spin) split into several levels according to the cubic symmetry as indicated. However, the actual crystal potential is not small at all; the most important plane-wave based method developed to circumvent this problem is the pseudopotential approach. In a crystal, the valence (or conduction) band wavefunctions are rapidly varying near each atomic site as they are orthogonal to those of the core states; therefore, their expansions in plane-waves are very slowly convergent. It is possible, though, to substitute them with pseudowavefunctions which are smooth (nodeless) near the atomic sites while replacing the ionic potential with a much smaller pseudopotential, in such a way that the energies $E_n(k)$ of valence and conduction band states can be computed using a limited number of plane-waves; furthermore, from the pseudowavefunctions, the electronic charge density outside the cores can also be obtained. The pseudopotential (or rather its first few Fourier components) can be empirically chosen to reproduce a set of significant data (mostly optical transition energies and effective masses). For instance, empirical calculations using only three Fourier components of the pseudopotential can already give a reasonable description of the lowest energy bands of elemental semiconductors. A significant improvement is obtained using energy dependent nonlocal pseudopotentials.

For state of the art *ab-initio* selfconsistent calculations, made possible by the great increase of computational capabilities, the pseudopotential method has also been very successful in conjunction with density functional theory in the local density approximation (LDA), i.e., using an exchange-correlation potential dependent only on the local electronic charge density. Such local density approximation is not quite satisfactory; in particular, the energy gaps of semiconductors are usually significantly underestimated (even though the shapes of both valence and conduction bands are well described). This shortcoming can be mended by going beyond the one-electron approximation and calculating quasi-particle selfenergies including (approximately) many-body effects, or adopting a time dependent version of density functional theory.

Band structures of Si, Ge and α -tin

The band structures of group IV elemental semiconductors show pronounced similarities and definite chemical trends. Strong analogies are expected in view of the identical configuration of the outermost electronic shell and of the identical crystalline symmetry. At the same time, going from Si to α -Sn, decreasing energy gaps accompany larger lattice constants due to the increasing size of the atomic cores.

The band structure of Si, qualitatively similar to that of diamond, is shown in Fig. 4 (Chelikowsky and Cohen, 1976) neglecting relativistic effects. The top of the valence band is at the Γ point and correspond to the $\Gamma_{25'}$ level (three times degenerate, spin excluded). The bottom of the conduction band is along the Δ line from the Γ to the X point at $k \simeq (2\pi/a)(0.85, 0, 0)$ and has Δ_1 symmetry (non degenerate, spin excluded). Thus, the conduction electrons have six pockets centered at the six equivalent conduction band minima (multivalley structure); they are ellipsoids of revolution elongated along the $\langle 100 \rangle$ directions with a

Fig. 4 Band structure of silicon from an empirical nonlocal (full line) or local (dotted line) pseudopotential calculation. From Chelikowsky JR and Cohen ML (1976). *Physical Review B* **14**: 556.

longitudinal mass $m_L \simeq 1.0 m$ and a transverse mass $m_T \simeq 0.2 m$, as measured from cyclotron resonance. A peculiarity of the band structure of silicon, showing up in its optical spectrum around 3.4 eV as discussed below, is the fact that along the Λ line from the Γ to the L point the higher valence band (of symmetry Λ_3) and the lowest conduction band (of symmetry Λ_1) are very nearly parallel.

The band structure of Ge is shown in Fig. 5 (Chelikowsky and Cohen, 1976) including the spin-orbit coupling interaction. This is a relativistic effect which, similarly to the atomic case, can reduce the degeneracy of the levels. For instance, without spin-orbit coupling, the top of the valence band would be, just as in Si, a p-bonding-like $\Gamma_{25'}$. In the presence of spin-orbit coupling, the sixfold degenerate states obtained from the $\Gamma_{25'}$ ones by the inclusion of spin are split into a fourfold degenerate Γ_8^+ level and a twofold degenerate Γ_7^+ level, which play the role, respectively, of $J = 3/2$ and $J = 1/2$ total angular momentum states. The corresponding spin-orbit gap is $\Delta = 0.3$ eV (the corresponding value for Si is only 0.04 eV). Besides spin-orbit splitting, other relativistic effects become more important in the heavier Ge than in Si; in particular, there are corrections affecting primarily s-derived states which lower their energy. These effects and the presence in the core of Ge of d electrons that, together with p electrons, contribute to push to higher energies the Γ_{15} states (corresponding to the Γ_8^- and Γ_6^- spin-orbit split states), through orthogonalization to the core states, explain why in Ge the s-derived Γ_2^- level (i.e., the Γ_7^- state, spin included) is lower than the Γ_{15} states. The interchange of the

conduction band energy level sequence at the Γ point with respect to Si is accompanied by the fact that the minimum of the conduction band in Ge occurs at the L point at the BZ border (the L_6^+ level). The conduction band of Ge therefore leads to a multivalley structure with four electron pockets (half pocket for each of the eight L points at the BZ border); they are ellipsoids of revolution elongated along the $\langle 111 \rangle$ directions. The values of the longitudinal mass $m_L \simeq 1.6 m$ and of the transverse mass $m_T \simeq 0.08 m$ have been determined from cyclotron resonance measurements.

The top of the valence band in both Si and Ge is at the center of the BZ: Γ_{25}' without spin, Γ_8^+ and Γ_7^+ including spin, as discussed above. The Γ_7^+ split-off hole states can be described as a simple band with an effective mass $m_{so} \simeq 0.25 m$ in Si and $m_{so} \simeq 0.08 m$ in Ge. In a rough approximation, the Γ_8^+ hole states can be described as belonging to two distinct spherical pockets each characterized by an isotropic mass: the heavy hole pocket (with mass $m_{hh} \simeq 0.5 m$ for Si and $m_{hh} \simeq 0.3 m$ for Ge) and the light hole pocket (with mass $m_{lh} \simeq 0.16 m$ for Si and $m_{lh} \simeq 0.044 m$ for Ge). Also these hole effective masses have been determined from cyclotron resonance measurements in low magnetic fields (classical regime). However, this simple picture is not quite correct: because of the valence band degeneracy, the hole bands are not isotropic, but “warped” (particularly, the heavy hole ones). A complete description of the hole states can be given using the multi-band effective mass approach, in which the valence band degeneracy is fully accounted for.

The tendency to have a lower energy s-derived Γ_7^- level is even stronger in gray tin where this level is positioned between the spin-orbit split Γ_8^+ and Γ_7^+ levels (“inverted gap” configuration). As a consequence, the band structure of α -Sn, shown in Fig. 6 (Chelikowsky and Cohen, 1976), is characterized by the fact that the fourfold degenerate (spin included) Γ_8^+ states correspond at the same time to the topmost filled valence band and to the lowest empty conduction band which touch each other at the Γ point. Grey tin is thus a “zero-gap semiconductor” rather than a semiconductor proper.

Comparison with experimental data

Just as for atoms and molecules, even for solids the most direct and informative experimental techniques to study their electronic structure over a wide range of energies are optical spectroscopy and photoelectron spectroscopy.

In crystalline semiconductors such as Si and Ge the absorption due to direct interband transitions is very strong and reflectivity measurements are more popular than transmission ones. From reflectivity spectra taken over a large frequency range it is possible to obtain the real and imaginary part of the complex dielectric function $\epsilon = \epsilon_1 + i\epsilon_2$ (via Kramers-Kronig analysis) and, thus, all the linear optical properties. From the theoretical point of view, the imaginary part $\epsilon_2(\omega)$ can be calculated summing over all possible transitions between filled (valence) states and empty (conduction) states corresponding to the absorption of a photon of frequency ω . As the wavelength of light is much larger than the lattice constant, such optical transitions take place between electronic states having the same wavevector within the first Brillouin zone (direct or “vertical” transitions) and differing in energy by $\hbar\omega$, thus:

Fig. 6 Band structure of α -Sn from an empirical nonlocal pseudo-potential calculation. From Chelikowsky JR and Cohen ML (1976). *Physical Review B* **14**: 556.

$$\varepsilon_2(\omega) = \frac{1}{\pi} \sum_{v,c} \int_{\text{BZ}} d^3k |d_{cv}|^2 \delta(E_c(\vec{k}) - E_v(\vec{k}) - \hbar\omega);$$

where d_{cv} is the transition electric dipole matrix element between the initial and final state. It is to be noticed that, because of the energy conserving delta function in the equation above, specific singularities in the frequency dependence of ε_2 are obtained when $\vec{\nabla}_k(E_c(\vec{k}) - E_v(\vec{k})) = 0$ (critical points). Such structures (many of which are dictated by symmetry alone) have been found in all elemental semiconductors, and this has allowed the identification of the critical point transition peaks and the verification of the band structure.

As a classical and pioneering example, we report in Fig. 7 (Brust et al., 1962) the optical excitation spectrum of Ge, measured as explained above and computed from the equation above on the basis of an empirical pseudopotential band structure calculation. We stress that not only have the critical points been identified, but also the full band structure has been put to test by the described analysis of the optical properties. A better resolution of the critical point behavior can be obtained by employing various kinds of modulation spectroscopy (e.g., piezorectance, electrorectance) that amounts to measure the first (or higher) derivatives of the dielectric function. As a further example, we consider a recent calculation of the optical absorption of Si shown in Fig. 8 (Onida et al., 2002) in comparison with experimental data. The time dependent density functional theory includes electron-hole correlations (i.e., excitonic effects) which are crucial to reproduce the conspicuous peak at about 3.4 eV associated with interband transitions near the L point.

The direct optical transitions discussed so far are usually dominant when allowed by energy conservation. It is however possible, through the absorption or emission of a phonon, to have indirect transitions in which the wavevector of the initial and final electronic states are different. These transitions are much weaker, but in the case of indirect gap semiconductors such as Si and Ge having the top of the valence band and the bottom of the conduction band at different points in the BZ they give rise to absorption at energies below the onset of the much stronger direct transitions. The corresponding (temperature dependent) characteristic features have been also observed and compared with theory providing additional evidence for the band structure determination.

Photoelectron spectroscopy has also proved to be a very useful experimental technique to measure the electronic structure of semiconductors. The photoemission process takes place through the following steps: first upon absorption of an incoming photon an electron is excited from a filled band to a higher empty band, then the excited electron travels toward the surface and, finally, if energetic enough, it escapes into the vacuum to be detected. Thus, low energy conduction states below the vacuum level are not involved in photoemission processes as they can be neither initial states (because empty in the ground state) nor final states (because unable to escape from the solid once excited). These levels can be investigated by inverse photoemission which is, in a sense, the time reversed process of photoemission: an incoming electron falls in an electronic level available in the solid emitting a photon which is then detected. In photoelectron spectroscopy, the energy, wavevector and polarization (spin) of the photon

(electron) can be selectively chosen or averaged over. The main advantage of photoemission and inverse photoemission with respect to optical spectroscopy is the capability of providing absolute energy levels rather than energy differences between levels. Besides lower resolution and (especially for inverse photoemission) lower statistics, the main disadvantage for the study of bulk properties is that photoelectron spectroscopy is much more surface sensitive because of the short escape or penetration depths of electrons (of the order of 10 Å).

The detailed analysis of angle resolved (inverse) photoemission data allows to obtain the complete band structure of a semiconductor. In Figs. 9 and 10 (Ortega and Himpfel, 1993), the energy bands of Si and Ge obtained by first principle quasi-particle calculations are compared with photoemission and inverse photoemission data showing very good agreement.

Direct gap elemental semiconductors

While the role of Si as the semiconductor of choice for all electronics applications cannot be disputed, its indirect gap hampers its potential use in light-emitting devices. Among elemental semiconductors, phosphorous (P, from group V) has an allotropic form with a direct gap, known as black phosphorous (bP), which is a layered orthorhombic crystal. As shown in Fig. 11, its direct gap of 0.3 eV opens at the Z point of its Brillouin zone, i.e., at the zone edge along the (001) direction, and the optical transition between the corresponding valence (Z_2^+) and conduction (Z_4^-) states is allowed, albeit polarization dependent (Qiao et al., 2014). Recently, bP has also attracted much interest (Carvalho et al., 2016) as it can be exfoliated into a monolayer (i.e., phosphorene).

Fig. 11 Band structure of black phosphorous. From calculations reported in Qiao J, Kong X, Hu Z-X, Feng Y and Ji W (2014). *Nature Communications* 5: 4475.

For optoelectronic applications, including lasing, it would be of paramount importance to integrate a direct gap semiconducting material on silicon chips. This long standing goal has been pursued employing, e.g., III-V semiconductors, SiGe alloys and also porous silicon (Zhou et al., 2015). Considering bulk elemental semiconductors, a promising candidate is hexagonal germanium (2H-Ge) that, differently from the common cubic crystal (c-Ge), has a direct band gap of 0.3 eV at the Γ point as shown in Fig. 12, with an allowed optical transition $\Gamma_{9v}^+ \rightarrow \Gamma_{8c}^-$. With respect to the band structure of c-Ge, this can be seen as the effect of folding the conduction band minimum from the L point to the Γ point. Most importantly, Si can be alloyed into 2H-Ge to form 2H-Si $_{\gamma}$ Ge $_{(1-\gamma)}$ which for $\gamma < 0.35$ maintains a direct gap tunable within the energy 0.3–0.7 eV (Fadaly et al., 2020).

Conclusion

All the main features of the band structure of elemental semiconductors are firmly established both from the theoretical and the experimental point of view. An overview of the field has been presented with illustrative examples taken from the main semiconductor families. These results represent one of the most important achievements in solid state physics and provide a framework within which not only virtually all material properties can be understood, but also novel materials can be designed (Giannozzi et al., 2009).

Abstract

Most semiconductors contain elements which have more than one stable isotope. The ability to manipulate the isotopic composition of semiconductors has made study of isotope effects possible. Phonon scattering and thermal conductivity are affected significantly by isotope disorder scattering, whereas there is a smaller, but measurable effect on bandgap. Use of isotope superlattices have enabled fundamental studies of solid-state diffusion. Spin coherence times are significantly lengthened in isotopically enriched material, which has significance for experimental realization of quantum computing concepts. Neutron transmutation enables precise and uniform control of doping in selected cases.

Key points

- Isotope effects due to atomic mass differences
- Isotope effects due to nuclear spin differences
- Isotope effects due to differences in thermal neutron capture cross sections.

Introduction

Close to 80% of the elements in the periodic table are multi-isotopic. Most semiconductors contain at least one element that consists of more than one stable isotope with Al, As, and P being important mono-isotopic exceptions (Berglund and Wieser, 2011). For example, silicon is composed of the three isotopes ^{28}Si , ^{29}Si , ^{30}Si with abundances of 92.23%, 4.67% and 3.10%, respectively. Gallium arsenide consists of mono-isotopic As and two Ga isotopes ^{69}Ga (60.11%) and ^{70}Ga (39.89%). Recent advances in isotope separation technology have led to the availability of semiconductors with controlled isotopic composition (Cardona and Thewalt, 2005). Very high levels of enrichment, >99.985%, have been achieved for ^{28}Si in the context of efforts to more precisely define Avogadro's constant (Becker et al., 2010).

Many physical properties of semiconductors depend on isotopic composition. Some of these are affected relatively weakly while others, thermal conductivity for example, can be influenced strongly. Here, we divide the isotope related effects into three groups: (1) those that are due to atomic mass differences between the isotopes; (2) those that are due to nuclear spin differences between isotopes; and (3) those that are due to differences in thermal neutron capture cross sections.

Atomic mass-related properties

Structure

The lattice constants of large, chemically pure and crystallographically highly perfect crystals can be measured with high precision x-ray diffraction techniques. As a consequence of zero-point motion atomic volumes are expected to change with isotopic composition. The

resulting effect on the lattice constant a_0 has been carefully studied for a number of elemental semiconductors including C, Si, and Ge which have the diamond structure. A theoretical analysis of the dependence of the lattice constant on isotopic composition at temperatures low compared to the Debye temperature of the material yields the following relationship (London, 1958):

$$\frac{\Delta a}{a} = -\frac{C}{a^3} \frac{\Delta M}{M} \left(\gamma_o \hbar \omega_o + \frac{3}{4} \gamma_a k_B \theta \right)$$

where C is the isothermal compressibility, M is the atomic mass, γ_o and γ_a are the Grüneisen parameters for optical and acoustic phonons, respectively, ω_o is the optical phonon frequency, k_B is Boltzmann's constant, and θ is the Debye temperature (constant mode Grüneisen parameters and a Debye frequency spectrum for the phonon modes are assumed). Evidently, the effect will be the largest for semiconductors with light atomic masses, large compressibilities, and high Debye temperatures. For context, the Debye temperatures of C, Si, and Ge are 2250 K, 645 K, and 374 K, respectively. Experimental data for diamond are shown in Fig. 1 (Holloway et al., 1991). The reduction of the lattice constant for ^{13}C diamond compared to ^{12}C diamond is 150 ppm, which is in qualitative agreement with the simple theory illustrated above. A more recent analysis uses first principles calculations to predict the temperature dependence of Δa_0 for C, Si, and Ge (Pavone and Baroni, 1994).

Phonon dispersion

A number of isotope effects in semiconductors are related to changes in the properties of phonons with atomic mass. A very simple harmonic analysis within the virtual crystal approximation predicts that the frequency ω of a given phonon should vary with the inverse square of the average mass M :

$$\omega \propto M^{-1/2}$$

As shown in Fig. 2 (Fuchs et al., 1992), this dependence is indeed observed for the zone-center optical phonon for a series of isotopically enriched single crystals of germanium with average masses between 70 and 76 amu (M of natural Ge is 72.59 amu).

Modern thin-film growth techniques have made isotopically engineered structures available to the experimentalist. Very interesting phonon effects can be observed in isotope superlattices (SLs), which consist of alternating layers with different isotopic composition. In contrast to SLs consisting of different materials such as GaAs and AlGaAs, the electronic band structure in isotope SLs is not significantly affected by the mass differences and the material looks bulk-like for electrons throughout the crystal layers. However, the changes in the phonon properties are sufficiently large to observe confinement effects.

A number of detailed experimental studies have been performed with Ge isotopes in structures consisting of a series of alternating sets of atomic planes of ^AGe and ^BGe where A and B are different atomic masses (Spitzer et al., 1994). Experimentally observed and theoretically calculated Raman spectra are compared in Fig. 3 for zone-center optical phonons for $^{70}\text{Ge}_n/^{74}\text{Ge}_n$ [001] oriented structures with n , the number of atomic layers, varying from 2 to 32. The Raman frequencies and mode mixing calculated by a simple bond-charge model and the force constants of natural Ge and the relative peak intensities determined by a bond polarizability approach are in good agreement with the experimental data. The shortest periods studied consisted of two atomic layers each and produce a single Raman line corresponding to the zone center optical phonon in a Ge crystal with $M = 72$ amu, the linear average of the two masses. That is, the phonon behavior is the same as in a bulk crystal with $M = 72$ amu. Confinement effects are observed at higher values of n as folded optical modes become Raman-active at the zone center. For example, in the

Fig. 1 Lattice constant of diamond as a function of isotopic composition at 25°C; the lattice constant decreases with increasing atomic mass. Adapted from Holloway H et al. (1991) Isotopic dependence of the lattice constant of diamond. *Physical Review B*, 44(13): 7123–7126, <https://doi.org/10.1103/PhysRevB.44.7123>.

Fig. 2 Zone center phonon observed by Raman spectroscopy at 90 K for single crystal germanium of varying isotopic composition. Dotted line shows the predicted $M^{-1/2}$ dependence. Adapted from Fuchs HD et al. (1992) Isotopic disorder-effects on the phonons in germanium. *Solid State Communications* 82(4): 225–228, [https://doi.org/10.1016/0038-1098\(92\)90631-1](https://doi.org/10.1016/0038-1098(92)90631-1).

Fig. 3 (A) Measured at $T = 10$ K and (B) calculated Raman spectra for a series of isotope superlattices $^{70}\text{Ge}_n/^{74}\text{Ge}_n$ grown along [001] with $n = 2, 4, 6, 8, 12, 16$, and 32. A number of modes confined to the ^{70}Ge and ^{74}Ge layers are evident. When there are only two ^{70}Ge and ^{74}Ge layers a single mode is observed. Adapted with permission from Spitzer J et al. (1994) Raman scattering by optical phonons in isotopic 70/74 (Ge) $_n$ -74(Ge) $_n$ superlattices, *Physical Review Letters* 72(10): 1565–1568, <https://doi.org/10.1103/PhysRevLett.72.1565>.

$n = 12$ superlattice at least three strong Raman lines are observed. For $n = 32$ the Raman spectra begin to approach the structure expected for two isotopically pure bulk crystals, one made up of ^{70}Ge , the other of ^{74}Ge .

Thermal conductivity

The most dramatic phonon-related isotope effect is found for the thermal conductivity. Pomeranchuk was the first to point out in 1942 that in a multi-isotopic material, minority isotopes must be treated as mass defects and that they will lead to scattering of acoustic phonons, reducing thermal conductivity with respect to a mono-isotopic material (Pomeranchuk, 1942). The first experimental measurements of what can be a very strong dependence of the thermal conductivity (which depends on acoustic phonons) on small degrees of isotopic disorder were performed in the late 1950s in germanium (Geballe and Hull, 1958). The most dramatic effect is found, however, in diamond. Fig. 4 illustrates the 5 fold increase in thermal conductivity found near 100 K in isotopically enriched ^{12}C (Wei et al., 1993). The measured value, $410 \text{ W cm}^{-1} \text{ K}^{-1}$, is the highest measured for any material above liquid nitrogen temperature (77 K).

The most successful modeling of the effect of isotopic disorder on thermal conductivity splits the thermal conductivity into four terms – normal, Umklapp, boundary, and isotope processes – which are inversely proportional to the phonon lifetime τ associated with the specific effect:

$$\begin{aligned}\tau_{\text{Normal}}^{-1} &= AvT^3 \lambda^{-1} \\ \tau_{\text{Umklapp}}^{-1} &= BvT^3 \lambda^{-1} \exp(-C/T) \\ \tau_{\text{Boundary}}^{-1} &= v/D \\ \tau_{\text{Isotope}}^{-1} &= 4\pi^3 v \lambda^{-4} V_0 x(1-x)(12+x)^{-2}\end{aligned}$$

where v and λ are the average phonon velocity and wavelength, x is the isotope fraction of ^{13}C , V_0 is the atomic volume, and A , B , C , and D are adjustable parameters. These relations not only can be used to reproduce the observed temperature dependence but can also predict the limits of thermal conductivity for samples with very high isotopic purity. Using this method, the inset in Fig. 4 shows the prediction of a thermal conductivity above $2000 \text{ W cm}^{-1} \text{ K}^{-1}$ for very highly enriched ^{12}C at 80 K.

Similar increases of the thermal conductivity at low temperature of the enriched semiconductors Ge and Si have been measured (Asen-Palmer et al., 1997; Inyushkin et al., 2018). Extremely highly enriched Si (99.995% of ^{28}Si) has a thermal conductivity of $450 \pm 10 \text{ W cm}^{-1} \text{ K}^{-1}$ at 24 K, which is the highest measured value for any bulk dielectric and is 10 times greater than that for Si with natural isotopic composition.

It is important to note that at temperatures well above the thermal conductivity maximum, the isotope-enrichment-related increases decline rapidly. For example, the increase in thermal conductivity at 300 K for highly enriched ^{28}Si compared to natural Si

Fig. 4 Thermal conductivity of natural abundance (1.1% ^{13}C) diamond (lower squares), isotopically enriched (0.1% ^{13}C) diamond (upper squares), together with the low temperature data of (Slack, 1973), (circles) and the high temperature data (Olson et al., 1993) (crosses). The solid curves are the result of fitting the Callaway theory described in the text. The inset shows the calculated thermal conductivity corresponding to 1%, 0.1%, and 0.001% ^{13}C concentrations according to the Callaway theory. Adapted with permission from Wei L et al. (1993) Thermal conductivity of isotopically modified single crystal diamond. *Physical Review Letters* 70(24): 3764–3767, <https://doi.org/10.1103/PhysRevLett.70.3764>.

is in the range of 10–15%. Increases in thermal conductivity have also been reported for compound semiconductors. SiC enriched to >99.5% in ^{28}Si and ^{12}C has an 18% higher thermal conductivity compared to natural abundance material (Lundqvist et al., 2013).

Varying the isotopic composition of a semiconductor allows for control of the thermal conductivity independent of its electrical conductivity, which is relevant to applications such as thermoelectrics (Bracht et al., 2014). Isotope heterostructures are also a convenient platform for experimental investigations. Additionally, boundary scattering reduces thermal conductivity at small spatial dimensions: the thermal conductivity of 50 nm Si nanowires is $100\times$ smaller than bulk Si at room temperature (Hochbaum et al., 2008). Interestingly, isotope effects can be very large at the nanoscale: ^{28}Si (99.92% enriched) nanowires have up to 150% higher thermal conductivity compared to natural abundance nanowires with similar diameters and surface morphology (Ci et al., 2022).

Electronic structure

Isotope composition affects the electronic structure through the electron-phonon coupling and through the change of volume with isotopic mass (see above section on lattice constants). The effect most often studied experimentally is the influence of isotopic mass on the band gap of the semiconductor. For example, using optical modulation techniques the isotope dependence of the direct and indirect bandgaps of germanium have been determined. The effect is small but satisfactorily predicted by theory (Davies et al., 1993).

Isotopically enriched Si allows for a careful comparison between theory and experiment. A sensitive way to measure the band gap dependence on M uses the very narrow no-phonon exciton photoluminescence (PL) lines found near the indirect gaps of Si and Ge. Measurements of the energies of these impurity bound excitons allow direct determination of band gap shifts because their radiative recombination does not require phonon participation. Furthermore, due to their large Bohr orbits, their energy depends only on the average isotopic mass and not on the isotopic disorder. Fig. 5A shows the change in the Si indirect bandgap measured using the phosphorus no-phonon line P_{NP} for a series of samples enriched in ^{28}Si , ^{29}Si and ^{30}Si (Karaïskaj et al., 2001).

In general, the contribution to the band gap shift from the isotopically induced volume change is the smaller of the two effects and can be addressed with the methods described above for the lattice constant effects. The analysis of the electron-phonon coupling effect is similar to that used to understand the change of band gap with temperature. The change is described by structure factors, which include electron-phonon interaction terms (Debye-Waller factors) and self-energy terms. These terms are then expanded in powers of the atomic displacements u . The leading terms are proportional to the mean-square displacements $\langle u^2 \rangle$. These, in turn, can be modeled as harmonic oscillators:

$$\langle u^2 \rangle = \hbar \left(\frac{1}{2} + n \right) / M\omega.$$

As temperature increases, n and thus $\langle u^2 \rangle$ increase, and the band gap is reduced. At low temperature, $n = 0$. Substituting the dependence of ω on M , we find

$$\langle u^2 \rangle \propto M^{-1/2}.$$

For increasing M , this analysis predicts decreasing $\langle u^2 \rangle$ and a bandgap increase, in agreement with observation.

For Si, combining photoluminescence and wavelength-modulated transmission spectra of phonon-assisted indirect excitonic transitions have enabled the most precise measurement of its fundamental bandgap. As shown by the measurements of ^{28}Si , ^{29}Si , and ^{30}Si in Fig. 5B, $E_{gx}(M = \infty) = (1213.8 \pm 1.2)$ meV, which is the purely electronic value in the absence of electron-phonon interaction and volume changes associated with anharmonicity (Tsoi et al., 2004). This value corresponds well to the best first

Fig. 5 (A) Effect of Si isotopic composition on the Si bandgap as observed by the shift of the P_{NP} PL line observed at 4 K as a function of isotopic enrichment. The bandgap increases with increasing atomic mass. The three curves are offset for clarity. (B) The excitonic indirect band gap of Si as a function of M . Adapted from Tsoi S et al. (2004) Electron-phonon renormalization of electronic band gaps of semiconductors: Isotopically enriched silicon. *Physical Review B. American Physical Society*, 70(19): 193201, <https://doi.org/10.1103/PhysRevB.70.193201>.

principles theory based on quasiparticle calculations (Zhu and Louie, 1991). A similar spectroscopic approach was used for the precise measurement of the E_0' and E_1 direct bandgaps of Si (Tsoi et al., 2005).

Self- and dopant diffusion

The study of self- and dopant diffusion in semiconductors has been advanced significantly through the use of isotopically controlled multilayer structures (Shaw, 2017). Diffusion measurements performed with radiotracer methods are limited by the half-lives of radioactive isotopes, by the damage produced during their introduction and by near surface effects. In contrast, the use of Secondary Ion Mass Spectrometry (SIMS) in isotope superlattice structures provides quantitative concentration profiles of the masses of the matrix as well as the dopant atoms.

In the simplest case two layers with different isotopes of a semiconductor are grown on a substrate of natural composition. The results of annealing such a structure are illustrated in Fig. 6 for a $^{nat}\text{Ge}/^{74}\text{Ge}/^{70}\text{Ge}/^{nat}\text{Ge}$ -substrate configuration (Fuchs et al., 1995). The ^{70}Ge concentration profile in the ^{74}Ge layer can be fitted with a simple complimentary error function (the solution to the 1-D

Fig. 6 Secondary Ion Mass Spectrometry (SIMS) profile of a $^{nat}\text{Ge}/^{74}\text{Ge}/^{70}\text{Ge}/^{nat}\text{Ge}$ -substrate structure before (top) and after annealing for 55.55 h at a temperature of 586 °C (bottom). The self-diffusion of the ^{70}Ge into the ^{74}Ge layer can be modeled with a simple complimentary error function to a very high level of precision. Adapted with permission from Fuchs, H. D. et al. (1995) Germanium 70Ge/74Ge isotope heterostructures: An approach to self-diffusion studies. *Physical Review B*, 51(23): 16817–16821, <https://doi.org/10.1103/PhysRevB.51.16817>.

simple Fick's law diffusion equation) over a range of four and one half orders of magnitude in concentration, yielding very precise self-diffusion data. Similar structures of silicon isotopes have been used to obtain precise measurements of the Si self-diffusion coefficient shown as a function of the absolute inverse temperature in Fig. 7 (Bracht et al., 1998).

The influence of the Fermi level (and hence of specific native defects) on self- and dopant diffusion has been studied with the aid of silicon isotope multilayers capped with an amorphous layer of natural silicon. Ion-implantation into the amorphous layer was used as a source of the desired dopant and to affect Fermi level control inside the structure. Such a dopant source has been found to produce only the expected electronic effects that are due to dopant-related shifts in Fermi level position. A representative SIMS result of silicon self- and As dopant diffusion is shown in Fig. 8. The modeling of the silicon isotope and the arsenic concentration profiles yields the unambiguous result that the negatively charged vacancy is the major native defect involved in the diffusion process.

Isotopically controlled compound semiconductor structures offer the possibility of observing self-diffusion of each of the constituent atoms. Using this method, a very spectacular result of self-diffusion has been reported for the III-V semiconductor GaSb (Bracht et al., 2000). Both host elements, Ga and Sb, have two isotopes occurring at comparable concentrations; a double-labeled $^{69}\text{Ga}^{121}\text{Sb}/^{71}\text{Ga}^{123}\text{Sb}$ heterostructure was used for the study. Fig. 9 shows the concentration profiles of the four

Fig. 7 Self-diffusion coefficient of Si measured using multilayer structures of the stable isotopes. Adapted with permission from Bracht H, Haller EE, and Clark-Phelps R (1998) Silicon self-diffusion in isotope heterostructures. *Physical Review Letters* 81(2): 393–396, <https://doi.org/10.1103/PhysRevLett.81.393>.

Fig. 8 Depth profiles of ^{30}Si (triangles) and As (circles) in an a-Si/ $(^{30}\text{Si}/^{\text{nat}}\text{Si})/^{\text{nat}}\text{Si}$ structure with 5 $^{30}\text{Si}/^{\text{nat}}\text{Si}$ periods, measured with Secondary Ion Mass Spectrometry (SIMS). Consistent modeling of both the dopant, As, and self-diffusion profiles (solid lines) shows that the singly negatively charged self-interstitial is the mediating native defect responsible for the diffusion of both species. Inset figure shows the SIMS depth profile of the as-grown isotope structure, with the same axis limits. Adapted with permission from Silvestri HH, PhD thesis, UC Berkeley 2004, unpublished.

Fig. 9 Concentration–depth profiles of Ga and Sb isotopes in GaSb isotope heterostructures measured with SIMS: ^{69}Ga (plus symbols), ^{71}Ga (crosses), ^{121}Sb (circles) and ^{123}Sb (squares). (A) Ga and Sb profiles of the as-grown $^{69}\text{Ga}^{121}\text{Sb}/^{71}\text{Ga}^{123}\text{Sb}$ heterostructure. (B, C) Profiles after annealing the isotope structure under Sb-rich conditions at 700 °C for 105 min (B) and 18 days (C). The Ga and Sb diffusion coefficients were determined by fitting the solution of Fick's law for self-diffusion across an interface to the Ga and Sb profiles measured after annealing. Solid lines in B and C show best fits. Adapted with permission from Bracht H et al. (2000) Large disparity between gallium and antimony self-diffusion in gallium antimonide. *Nature* 408(6808): 69–72, <https://doi.org/10.1038/35040526>.

isotopes ^{69}Ga , ^{71}Ga , ^{121}Sb and ^{123}Sb for the as-grown structure and after thermal annealing at different times and temperatures. The Ga host atoms diffuse by a factor of ~ 1000 faster than the Sb atoms. Even after 4 days at a temperature just under the bulk melting point of GaSb and long after the labeled Ga atoms have diffused into the bulk, the Sb atoms have barely moved. The large difference can be explained with the formation of Ga_{Sb} antisites that suppress the formation of Sb vacancies required for the diffusion of this constituent.

Local vibrational modes

The vibrations of light impurity atoms in a semiconductor can occur at much higher frequencies than the maximum single phonon frequencies of the host lattice. In this case, the coupling to the host lattice is weak, such that this local vibrational mode (LVM) can have a long lifetime and a very narrow spectral linewidth as observed by infrared absorption, Raman scattering, or other techniques. Depending on the details of the lattice location of the impurity, particularly on symmetry and on how many bonds are formed with host lattice atoms, a number of normal vibrational modes are observed. Because of the simple dependence of vibrational frequencies on the inverse square root of the vibrating mass, isotope substitution of the impurity is used to obtain unambiguous proof for the association of an LVM feature with a certain impurity. The largest isotope shift caused by such a substitution of stable isotopes is close to 40% and is obtained for hydrogen substituted by deuterium.

In order to obtain a crude understanding of an LVM spectrum, it usually suffices to model the impurity and the nearest bound neighbors as a quasi-molecule imbedded in the host crystal. The model can be improved substantially by taking into account next

Fig. 10 (A) Spectrum of the Ge_2O quasi molecules in natural Ge at 2.05 K. Eleven lines split by $\nu_2 + \nu_3$ coupling excitations correspond to the distinct isotopic mass combinations of the two Ge atoms in the quasi molecule. An oxygen free sample produced the dashed line. (B) The spectrum of an oxygen doped, highly enriched sample of ^{70}Ge . The lines labeled ^{71}Ge are caused by traces of ^{72}Ge in ^{70}Ge . Adapted with permission from Mayur AJ et al. (1994) Fine structure of the asymmetric stretching vibration of dispersed oxygen in monoisotopic germanium. *Physical Review B* 49(23): 16293–16299, <https://doi.org/10.1103/PhysRevB.49.16293>.

nearest neighbor atoms in the form of an additional mass correction, the “host interaction mass” and by extending the linear force dependence on impurity displacement with higher terms (anharmonicity). When the host lattice consists of several stable isotopes with some of these present at significant atomic fractions (Ge is an example), LVM spectra can contain many closely spaced or overlapping lines because the impurity and its host lattice neighbors form quasi-molecules with a number of different reduced masses. Isotope enrichment of the host material can lead to drastic simplification of the LVM spectra in such cases. This is illustrated in Fig. 10 for the LVM of oxygen in Ge (Mayur et al., 1994). Taking into account two nearest neighbors, the $^x\text{Ge}-\text{O}-^y\text{Ge}$ molecule has three fundamental modes. The “wag” mode (ν_3) has the highest frequency. It leads to 11 lines resulting from the different mass combinations of ^xGe and ^yGe , each one split into several components whose intensities depend on temperature. Isotopic enrichment not only greatly simplifies the spectrum (one split line is observed instead of 11), it also allows a quantitative study of the linewidth and of the coupling between ν_2 and ν_3 modes and as a function of temperature. In this way, it was shown that the observed splitting is a result of the nonlinear superposition of the ν_2 and ν_3 modes and that the temperature dependence is due to the thermal population of low frequency ν_2 mode, which can be significant, even at near liquid helium temperature.

Spin-related properties

A number of elements found in typical semiconductors have half-odd nuclear spins I and hence magnetic moments. Examples are ^{73}Ge ($I = 9/2$), ^{29}Si ($I = 1/2$), ^{31}P ($I = 1/2$), and both stable isotopes of Ga: ^{69}Ga ($I = 3/2$) and ^{71}Ga ($I = 3/2$). The magnitude of the magnetic moment and the spin-lattice (T_1) and transverse (decoherence, T_2) lifetimes of non-equilibrium nuclear spin populations are measured with nuclear magnetic resonance (NMR). In high-quality single crystal material, lifetimes can be long. For example, the spin lattice relaxation time of the ^{29}Si (4.67% natural abundance) nuclear spin can be as long as several hours at room temperature (Shulman and Wyluda, 1956); decoherence times can be as long as 25 s at cryogenic temperatures in ultrahigh purity single crystals (Ladd et al., 2005).

In the case of electron spin resonance (ESR), soon after the demonstration of the effect in the late 1950s, the effects of isotopic enrichment on the spin dynamics of donor electrons bound to ^{31}P were investigated. At that time, a doubling of T_2 from 0.2 to 0.5 ms was observed by removing the hyperfine spin orbit coupling interaction between the electron spin and the nuclear spin of the ^{29}Si (Feher et al., 1958). Modern measurements on higher purity $>99\%$ ^{28}Si enriched material have demonstrated $T_2 > 100$ s (Steger et al., 2012).

These and related effects are expected to be important in developing solid state quantum computing schemes based on electron and/or nuclear spin as qubits (Kane, 1998). Highly enriched ^{28}Si is extremely valuable for experimental work in this area, as it can be thought of as a “semiconductor vacuum,” with properties almost identical to those of Si, but with almost no nuclear spins, and optical linewidths approaching their homogeneous, lifetime-limited values (Steger et al., 2012). It is also possible to use both the electron and nuclear spin on ^{31}P in experimental demonstrations of quantum information. Fig. 11 depicts the coherent transfer of a superposition state in an electron-spin “processing” qubit to a nuclear-spin “memory” qubit, using a combination of microwave

Fig. 11 Coherent storage of an electron-spin state in a nuclear-spin state, using a ^{31}P -doped ^{28}Si -enriched silicon single crystal. (A) The general sequence for the storage and revival of the electron-spin state comprises microwave and RF pulses with relative timings defined by τ_{e1} , τ_{e2} and τ_n . (B) Electron-spin coherence is stored in the nuclear spin for $2\tau_n \approx 50$ ms, at 7.2 K. Real (red) and imaginary (black) parts of the recovered electron-spin echo are shown for different initial phases ϕ . The echo is of comparable intensity to that obtained at the beginning of the sequence, even though the electron-spin coherence time, T_{2e} , is considerably shorter, about 5 ms. The lifetime of the stored state is limited instead by the considerably longer nuclear decoherence time, T_{2n} . (C) Measurements of the recovered echo intensity as a function of the storage time at 5.5 K yield a T_{2n} exceeding 1 s. Adapted with permission from Morton JLL et al. (2008) Solid-state quantum memory using the ^{31}P nuclear spin. *Nature* Macmillan Publishers Limited. All rights reserved 455(7216): 1085–1088, <https://doi.org/10.1038/nature07295>.

and radio-frequency pulses applied to ^{31}P donors in an isotopically pure ^{28}Si crystal (Morton et al., 2008). The state is left in the nuclear spin on a timescale that is long compared with the electron decoherence time, and is then coherently transferred back to the electron spin, thus demonstrating the ^{31}P nuclear spin as a solid-state quantum memory with a lifetime of over 1 s.

Neutron transmutation doping

The extreme versatility of semiconductors in their wide range of applications is based on our ability to dope these solids with donors and acceptors. For device fabrication dopants are introduced at or near the surface either by diffusion or by ion implantation. Bulk crystal doping is typically achieved by adding the appropriate minute quantities of dopant elements to the melt from which the crystal is pulled. An alternative doping technique is neutron transmutation doping (NTD).

The radioactive decay of an isotope of one element into an isotope of a different element forms the foundation of NTD of semiconductors. We illustrate NTD of Si here. The NTD process is typically performed in a nuclear reactor. During exposure of natural silicon to thermal neutrons (n_{th}) all three isotopes capture neutrons with well known capture cross sections, and the following reactions occur:

The third reaction leads to the formation of the donor P. NTD differs from other dopant technologies in that very high doping uniformity can be obtained. The unmatched doping uniformity achieved by NTD is based on three factors. First, the stable isotopes are truly randomly distributed in a semiconductor of natural composition. Second, the source of thermal neutrons is typically larger than the semiconductor crystal to be doped. This, in turn, leads to a large homogenous thermal neutron field guaranteeing identical exposure of all parts of the crystal. Third, the capture cross section for thermal neutrons is typically of the order of a few barns ($1 \text{ b} = 10^{-24} \text{ cm}^2$) which means that a few centimeters of material absorb the thermal neutron flux by significantly less than 1%, maintaining the nearly uniform neutron flux throughout the depth of the sample.

Fig. 12 Extrapolated zero temperature electrical conductivity (right axis) and characteristic temperature T_0 (left axis) for variable range hopping for 14 samples with carefully controlled concentrations of ^{71}Ga -doped ^{70}Ge made with neutron transmutation doping. The metal insulator transition (MIT) is found to occur at an acceptor concentration of $1.86 \times 10^{17} \text{ cm}^{-3}$. Adapted with permission from Itoh KM et al. (1996) Hopping conduction and metal-insulator transition in isotopically enriched neutron-transmutation-doped $^{70}\text{Ge}:\text{Ga}$. *Physical Review Letters* 77(19): 4058–4061, <https://doi.org/10.1103/PhysRevLett.77.4058>.

For this reason, semiconductors that are used in high power, high voltage applications, such as Si rectifiers (SCRs), are manufactured using NTD Si (von Ammon, 1992). Scientifically, NTD enables researchers to more precisely control doping levels. For example, it is possible to precisely dope Ge with Ga very close to the metal-insulator transition (MIT). As shown in Fig. 12, it was found that the critical concentration was $1.86 \times 10^{17} \text{ cm}^{-3}$ when the MIT was approached from both above and below (Itoh et al., 1996). Also, instrumentation for far infrared and submillimeter wave astronomy and astrophysics have profited from NTD. Small temperature sensing elements of crystalline NTD germanium are assembled into large arrays in the focal planes of all modern far IR telescopes (Haller, 2006).

Conclusion

An overview of the effect of the distribution of stable isotopes has been provided. Most effects are due to differences in atomic mass. In general, the lattice constant increases with increasing mass, as can be seen in diamond whose average atomic mass can be controlled between 12 and 13 amu and in silicon where control between 28 and 30 amu is possible. Phonons are relatively strongly affected by isotopic disorder and isotopically enriched material can have significantly enhanced thermal conductivity. Electronic properties are affected but less strongly. However, use of isotopic control allows for quantification of fundamental bandgaps, which is the purely electronic value in the absence of electron-phonon interaction and volume changes associated with anharmonicity. Isotopically controlled heterostructures have been invaluable in the study of solid-state diffusion and in the spectroscopy of local vibrational modes. Linewidths of optical transitions and electron spin lifetimes are significantly enhanced in isotopically enriched Si, which has enabled a number of compelling demonstrations in quantum information science. In certain cases, neutron transmutation doping is possible, and precise control and uniformity of doping can be achieved.

Abstract

Polaritons are elementary excitations describing light strongly coupled to material resonances ('light-matter waves'). This chapter reviews basic properties of polaritons in condensed media of various dimensions and at interfaces. It also discusses the effect of spatial dispersion, Bose–Einstein condensation of cavity polaritons and dark-state polaritons in gases.

Key points

- Electromagnetic waves in a condensed medium can strongly couple to dipole-active resonances of the medium, forming hybrid excitations known as polaritons.
- The article reviews two complementary frameworks, the semi-classical approach and the second quantization formalism, that conveniently describe polaritons.
- The number of polaritonic modes at a given frequency is determined by spatial dispersion of the resonant material excitation.
- General properties of polaritons depend more on the geometry of the solid than on the character of the material excitation that couples to light. We will discuss polaritons in a variety of geometries, including low-dimensional structures.

Introduction

Definition

Polaritons are quasiparticles (elementary excitations in a condensed medium) that form as a result of interaction and mixing of light with dipole-active transitions of the medium. The classical theory of light waves in ionic crystals near optical phonon frequencies was proposed by Tolpygo (1950) and Huang (1951) in the early 1950s. Later, the quantum theory of light waves near excitonic resonances and the concept of polaritons were developed in works by Fano (1956), Hopfield (1958), and Agranovich (1959).

Consider an electromagnetic wave propagating in a medium, and let the frequency of the wave be close to some resonance frequency of that medium. These resonances are generally associated with some elementary excitations of the medium

[☆]Change History: March 2022. M. Litinskaya updated figures, added 'Key points' and 'Conclusions,' corrected minor typos, revised the whole text, updated the chapter 'Cavity Polaritons' to include some of modern research directions, and revised section 'Surface polaritons'; 4 papers were added to the list of references, and 2 to further reading list. April 2015. M. Litinskaya added Keywords, Abstract, a few paragraphs into the section 'Cavity polaritons' and a section 'Dark-state polariton,' and updated the address. The list of literature was split into References and Further reading, with four additional items added. April 2019. M. Litinskaya revised the whole text and updated the chapter 'Cavity Polaritons' to include some of modern research directions. Seven papers were added to the list of references.

Fig. 1 Dispersion of bulk exciton-polaritons (thick red lines) and of the longitudinal wave (short-dash green lines). The polaritonic splitting, 2Δ , is shown by the black arrow in panel (A). The numbers in brackets indicate the degeneracy of each mode. Long-dash blue lines show the dispersions of ‘bare’ photon and ‘bare’ transverse exciton. (A) Spatial dispersion is neglected. The inset shows the exciton and photon weight coefficients $|C_{\text{exc}}^{(L)}(k)|^2$ and $|C_{\text{phot}}^{(L)}(k)|^2$ for the lower polaritonic branch (they are defined in Eq. 2). (B) Spatial dispersion is taken into account, and $m_t > 0$, $m_l > 0$. Here and below the plots are not to scale. The inset shows the spectrum of transverse waves for $m_t < 0$, with ω_M being the maximum frequency of the lower polariton branch.

(quasiparticles). They can be of electronic nature, such as Frenkel or Wannier–Mott excitons, or lattice vibrations, such as optical phonons in ionic crystals. The electromagnetic field polarizes the medium, and the polarization, which is high near the resonance frequency, in turn influences the electromagnetic field. One can regard it as an interaction between the ‘bare’ photon and ‘bare’ medium excitation (hence the term ‘light-matter interaction’). When the interaction is strong enough, the excitation spectrum of the medium essentially changes. Near the resonance between the light mode and the medium excitation, their ‘bare’ dispersion curves transform into two – the ‘lower’ and the ‘upper’ – split modes known as polaritonic branches. These hybrid modes show anticrossing behavior, so that a gap of the size 2Δ , where Δ is the coupling strength defined below, opens in the excitation spectrum (see Fig. 1). This situation is referred to as the ‘strong-coupling regime.’ Polaritons inherit the properties of both ‘bare’ photons and ‘bare’ medium excitations, and this mixed – half-light, half-matter – character of polaritons leads to many interesting physical properties.

In solids, the type of crystal excitation, which participates in the formation of polaritons, is encoded in a prefix: ‘exciton-polaritons,’ ‘plasmon-polaritons,’ and ‘optical phonon-polaritons.’ The quasiparticles, which appear as a result of interaction between the electromagnetic field and the resonances of magnetic permeability, are known as ‘magnetic polaritons.’ In gases, the term ‘polariton’ is widely used to describe the coupled state of electric field and atomic or molecular transitions in the gas.

Theoretical approaches

Many processes with the participation of polaritons, as well as their dispersion law, can be described within the macroscopic semiclassical approach using the system of Maxwell’s equations for the electromagnetic fields in the medium. For spatially restricted systems, the problem must be supplemented by the fields outside the crystal and by proper boundary conditions. These equations are combined with the material equation, which connects the fields $\mathbf{D}$ and $\mathbf{E}$ through the tensor of dielectric permittivity $\varepsilon_{ij}(\omega, \mathbf{k})$. The tensor $\varepsilon_{ij}(\omega, \mathbf{k})$ that describes the response of the medium is obtained from the microscopic theory or from experiment. In general, in an infinite homogeneous isotropic medium with the account of spatial dispersion,

$$\varepsilon_{ij}(\omega, \mathbf{k}) = \varepsilon_t(\omega, \mathbf{k}) \left(\delta_{ij} - \frac{k_i k_j}{k^2} \right) + \varepsilon_l(\omega, \mathbf{k}) \frac{k_i k_j}{k^2} \quad (1)$$

where ω is the frequency, $\mathbf{k}$ is the wave vector, $\varepsilon_t(\omega, \mathbf{k})$ and $\varepsilon_l(\omega, \mathbf{k})$ are transverse and longitudinal dielectric permittivities, and δ_{ij} is the Kronecker symbol. The condition $\varepsilon_l(\omega, \mathbf{k}) = 0$ determines the dispersion $\omega = \omega_l(k)$ of a longitudinal wave, which does not interact with transverse photons. In turn, the poles $\omega = \omega_t(k)$ of the function $\varepsilon_t(\omega, \mathbf{k})$ determine transverse ‘bare’ excitations of the medium (excitons, plasmons or optical phonons). As shown below, polaritons are the transverse normal modes (i.e., the solutions of Maxwell’s equations) of the medium near these frequencies. The macroscopic description holds as long as the wavelength of light strongly exceeds the lattice constant and the excitonic Bohr radius.

In the framework of the alternative microscopic (quantum) approach, polaritons appear due to account of retardation. Excitons are collective electronic material excitations in the approximation when only the instantaneous Coulomb interaction between the molecules (or atoms) is considered (i.e., in the limit $c \rightarrow \infty$). Retardation, as known from quantum electrodynamics, is equivalent to taking into account the interaction with transverse electromagnetic field. Hence, polaritons appear as a result of interaction

between excitons and transverse photons. This approach utilizes the second-quantization formalism, where polaritons are the eigenstates of the full Hamiltonian of the crystal, which is a sum of the Hamiltonians of 'bare' transverse photons, 'bare' excitons, and the Hamiltonian of their interaction. The polariton operators are linear combinations of the operators of 'bare' photons and 'bare' excitons. Near the resonance, these operators are

$$\begin{aligned}\zeta_{k,\rho}^+ &= C_{\text{phot}}^{(\rho)}(k)a_k^+ + C_{\text{exc}}^{(\rho)}(k)B_k^+ \\ \zeta_{k,\rho} &= C_{\text{phot}}^{(\rho)*}(k)a_k + C_{\text{exc}}^{(\rho)*}(k)B_k\end{aligned}\quad (2)$$

where a_k^+ , a_k and B_k^+ , B_k are the creation and annihilation operators of photons and excitons, and $\rho = \text{U, L}$ denote the upper or the lower polaritonic branch. The coefficients $C_{\text{phot}}^{(\rho)}(k)$ and $C_{\text{exc}}^{(\rho)}(k)$ are the amplitudes of the photon and the exciton in each polaritonic state, and their squared modules are the weights of the 'bare' excitations in the polaritonic states. They vary between 0 and 1 with the change of the wave vector k , and at the resonance

$$|C_{\text{phot}}^{(\text{U,L})}(k_{\text{res}})|^2 = |C_{\text{exc}}^{(\text{U,L})}(k_{\text{res}})|^2 = 1/2$$

Within linear optics, these two approaches yield identical results, and the choice between them is a matter of convenience. The semiclassical (macroscopic) approach is often used to calculate the optical response, while quantum (microscopic) formalism is convenient for studies of non-linear processes. Quantum description is also used to discuss the collective properties of polaritons and their statistics, and for the description of the eigenfunctions of the crystal (in particular, the polaritonic vacuum state is not equivalent to an independent-particle vacuum). Furthermore, quantum description is valid for low-dimensional structures (such as a monolayer, or a chain of molecules), when a dielectric tensor cannot be introduced, and the macroscopic description is not valid.

Strong coupling, weak coupling, and ultrastrong coupling

The strong-coupling regime can be destroyed by various dephasing processes. Many of them (such as exciton–phonon interactions and scattering of polaritons by structural disorder) act on polaritons through their material (excitonic) component. In addition, the lifetime of polaritons is restricted by finite lifetime of the photon within the finite-size crystal. The strong-coupling regime holds as long as the exciton–photon coupling strength Δ exceeds all the involved dephasing rates. If this condition is violated, the system is in the so-called weak-coupling regime, when the gap in the spectrum of elementary excitations does not form. In the quantum language, the strong-coupling regime is described by vacuum Rabi oscillations (reversible exchange of energy quanta between light and matter 'bare' states), whereas the weak-coupling regime corresponds to irreversible spontaneous decay of the collective 'bare' material excitations of the medium. In the strong-coupling regime the polariton splitting Δ is a small fraction of the frequency of the material excitation, ω_t . Since recently, a new regime – ultrastrong coupling, with the coupling strength Δ and excitation frequency ω_t being of the same order – became experimentally available.

The impact of phonons can be diminished by decreasing the temperature. For instance, in good GaAs crystals, the strong coupling regime holds below 20 K in bulk, and below 70 K in microcavities. Disorder appears as impurities in bulk crystals, and interface roughness and/or alloy fluctuations for cavity- and surface polaritons. The main effect of disorder is that it introduces local excitonic levels, which trap polaritonic states and eventually can destroy them. In the state-of-the-art optical microcavities, the role of disorder can be brought almost to nothing.

Polaritons in bulk

Dispersion equation

In the framework of the macroscopic approach, the dispersion equation for polaritons in a bulk (3D) medium can be obtained by solving the wave equation for the fields D and E :

$$\Delta E + \frac{\omega^2}{c^2}D - \text{grad div } E = 0 \quad (3)$$

combined with a material equation. In a uniform isotropic medium, where the wave vector k conserves, and neglecting the dissipation, the dielectric permittivity $\epsilon_t(\omega, k)$ near an electronic transition is

$$\epsilon_t(\omega, k) = \epsilon_b + \frac{A}{\omega^2(k) - \omega^2} \quad (4)$$

where ϵ_b is the background dielectric constant, and A is proportional to the oscillator strength f_{osc} of the transition. Dropping the resonance term would describe 'bare' photon in that medium. Furthermore, $\omega_t(k)$ is the dispersion of the crystal excitation, which, for small k , we can write in the effective-mass approximation:

$$\omega_t(k) = \omega_t + \frac{\hbar k^2}{2m_t}, \quad \omega_t \equiv \omega_t(k=0) \quad (5)$$

Here m_t is the effective mass of the material excitation, it determines the curvature of its dispersion. If the dependence of the dielectric permittivity on the wave vector (i.e., spatial dispersion) is neglected, then $\omega_t(k) = \omega_t$ and $\varepsilon_t(\omega, k) \equiv \varepsilon(\omega)$. This approximation works well for optical phonon–polaritons and some of Frenkel exciton–polaritons, while for Wannier–Mott exciton–polaritons the dependence of $\varepsilon_t(\omega, k)$ on k is usually important.

In an infinite isotropic medium, the wave equation, Eq. (3), has three solutions. One is a longitudinal wave, and its dispersion law $\omega = \omega_l(k)$ is determined by $\varepsilon_l(\omega, k) = 0$. In addition, there are two twice-degenerate (corresponding to two possible polarizations) transverse waves, which are polaritons. Their dispersion law can be found from the equation

$$\frac{c^2 k^2}{\omega^2} = \varepsilon_t(\omega, k) = \varepsilon_b + \frac{A}{\omega_t^2(k) - \omega^2} \quad (6)$$

which for $\omega \sim \omega_t$ simplifies as

$$(\omega - \omega_{\text{phot}}(k))(\omega - \omega_t(k)) = \Delta^2 \quad (7)$$

where $\Delta = \sqrt{A/(4\varepsilon_b)} \propto \sqrt{f_{\text{osc}}}$ is the light-matter coupling strength, and $\omega_{\text{phot}}(k) = ck/\sqrt{\varepsilon_b}$ is the dispersion of the photon in the crystal. Near the resonance (i.e., for $\omega \sim \omega_t(k) \approx \omega_{\text{phot}}(k)$), the polaritonic branches anticross. The smallest separation between them is at the resonance, and is equal to 2Δ . Far from the resonance, the polaritonic effect is negligible, and polaritonic dispersion curves approach the dispersion curves of the bare photon and material excitation. The solutions of (7) $\omega = \omega_{U,L}(k)$ are

$$\omega_{U,L}(k) = \frac{1}{2} \left[\omega_{\text{phot}}(k) + \omega_t(k) \pm \sqrt{(\omega_{\text{phot}}(k) - \omega_t(k))^2 + 4\Delta^2} \right] \quad (8)$$

The dispersion curves of bulk exciton-polaritons are plotted in Fig. 1 together with ‘bare’ excitations and the longitudinal wave, which does not couple to light ((A) without and (B) with spatial dispersion). These modes have been seen in many semiconductors (such as CuCl, GaAs, CdS) in a variety of optical experiments (for instance, two-photon absorption measured at different angles or hyper-Raman scattering measurements).

Anisotropic media

Some of Frenkel excitons have large oscillator strength and hence interact strongly with light. Organic molecular crystals, which support Frenkel excitons, are optically anisotropic. The properties of polaritons in anisotropic crystals are determined by the structure of the dielectric tensor $\varepsilon_{ik}(\omega, \mathbf{k})$ of the crystal (see Eq. 1), which relates the fields $\mathbf{D}$ and $\mathbf{E}$ as

$$D_i(\omega, \mathbf{k}) = \varepsilon_{ik}(\omega, \mathbf{k}) E_k(\omega, \mathbf{k})$$

Then the equation analogous to (6), which yields the dispersion of polaritons $\omega = \omega(k)$, can be obtained from the zeros of the following determinant:

$$\left| \frac{\omega^2}{c^2} \varepsilon_{ik}(\omega, \mathbf{k}) - k^2 \delta_{ik} + k_i k_k \right| = 0 \quad (9)$$

For an arbitrary direction of the wave vector $\mathbf{k}$, polaritons in anisotropic crystals have a mixed longitudinal–transverse character.

Spatial dispersion and additional waves

Spatial dispersion, which manifests as dependence of dielectric permittivity ε on the wave vector, reflects the ability of the material excitations to propagate in the crystal due to internal interaction forces. If spatial dispersion is neglected, then there are no bulk waves in the frequency interval $\omega_t < \omega < \omega_l = \omega_l(0)$, and for all other frequencies the dispersion equation allows for a single propagating bulk wave. In other words, all the frequencies ω and wave vectors k are in one-to-one correspondence (see Fig. 1A). The account of spatial dispersion corresponds to finite (as opposed to infinite) effective mass of the material excitation, m_v , and hence results in bending of the dispersion curves of ‘bare’ material excitations, so that near the resonances, at the concave side of the dispersion curve, one-to-one correspondence between the wave vectors and frequencies becomes broken (Fig. 1B). As a result, in narrow frequency intervals near the resonances, more than one wave can propagate at a given frequency. The existence of large-wave-vector waves, which appear in addition to “regular” small-wave-vector polaritons, was first pointed out by Pekar (1957). They are called ‘additional waves.’

The spatial dispersion shows up as the wave vector dependence of the excitonic resonance, as in Eq. (5) (isotropic medium is assumed). The curve $\omega_t(k)$ bends up or down, depending on the sign of m_t . The curve $\omega_l(k)$ also bends up or down depending on the sign of the effective mass m_l of the longitudinal exciton, since in general $m_l \neq m_t$. According to the signs of m_l and m_v , a number of scenarios emerge. Some examples are given below. For instance, in an isotropic nongyrotropic medium with $m_t > 0$, for $\omega > \omega_l$, there always exist two propagating transverse waves, a small-wave-vector upper polariton and a large-wave-vector lower polariton (see Fig. 1B). A lower polariton state exists also in the ‘forbidden’ region ($\omega_t < \omega < \omega_l$). In Fig. 1B, m_l is taken to be positive, that is typical for inorganic semiconductors. Then for $\omega > \omega_l$ the longitudinal wave coexists with two transverse polaritons. As another example, consider $m_t < 0$, which holds in some molecular crystals. Now there are two propagating transverse waves (both are lower-branch polaritons) for $\omega < \omega_M < \omega_t$ (see the inset in Fig. 1B). Out of these two waves, the polariton with the larger wave vector has a negative

Fig. 2 Dispersion of bulk polaritons (thick red lines) in a gyrotropic cubic crystal. Dashed blue lines show the dispersion of ‘bare’ excitons and ‘bare’ photon, ω_G is the maximum frequency of the lower polariton branch.

group velocity, and therefore at interfaces it exhibits unusual refraction known as ‘negative refraction.’ As for the longitudinal wave (not shown in the inset), for $m_l > 0$ it exists at $\omega > \omega_l$ together with the upper polaritonic branch, while for $m_l < 0$ the longitudinal wave is the third wave at $\omega < \omega_M$, and it is the only one wave at $\omega_M < \omega < \omega_l$. Yet one more interesting case to consider is a cubic gyrotropic crystal, where the dispersion curve of the exciton splits into two branches with linear dispersions: $\omega_e^{(\pm)}(k) = \omega_e \pm \alpha k + O(k^2)$. The corresponding polaritonic spectrum with three propagating waves at $\omega < \omega_G < \omega_l$ and one propagating wave at $\omega > \omega_G$ is shown in Fig. 2. Again, the polaritonic branch, which asymptotically follows $\omega_e^{(-)}(k)$, exhibits negative refraction.

For spatially restricted media (e.g., when calculating the reflectance of a bulk crystal) at the frequencies where the one-to-one correspondence between ω and k is broken and an additional wave or waves exist, one has to introduce the so-called additional boundary conditions (ABCs), since usual Maxwell’s boundary conditions are not sufficient to find the relation between the amplitudes of the waves. From a microscopic point of view, ABCs describe the behavior of the fields close to the surface. The character of ABCs essentially depends on the properties of the medium, its surface, and on the properties of the material excitations (excitons). In the most general case, in the framework of linear optics, ABCs are constructed as some linear combinations of the fields E , P and their derivatives. The first ABC proposed by Pekar (1957) is $P = 0$ at the boundary of the medium. It is good for molecular crystals, but is often suitable also for semiconductors. A widely used approach proposed by Hopfield and Thomas (1963) introduces a ‘dead layer’ of some thickness l near the surface, where excitons cannot penetrate. The thickness l and other phenomenological constants entering ABCs are to be determined from a microscopic theory or from comparison with experiment.

Surface polaritons

Surface polaritons are normal modes that propagate along the surface of the medium, or along an interface between two media, or along interfaces of layered structures. The electromagnetic field in these modes decays exponentially with the distance from the surface. As shown below, surface polaritons require the dielectric permittivity of the medium to be negative, which is possible near a resonance frequency of the medium. Surface polaritons can give us information about the surface of the crystal. Furthermore, they may be important as possible final states in various processes of interaction or scattering of electromagnetic waves in crystals.

Surface polaritons at the interface between two semi-infinite media

Let a semi-infinite isotropic medium with the dielectric permittivity $\varepsilon(\omega)$ (spatial dispersion is neglected) be in contact with an isotropic half-space with the dielectric constant ε_{out} . Let $k_{||}$ be a two-dimensional wave vector parallel to the surface. The surface mode is TM-polarized (see the inset in Fig. 3) and has the following dispersion relation:

Fig. 3 Red solid line: graph of the function $\varepsilon(\omega)$. At the interface between the materials with the dielectric permittivities $\varepsilon(\omega)$ and ε_{out} , surface polaritons exist at the frequency interval $\omega_t < \omega < \omega_s$ highlighted in blue, where $-\varepsilon_{out} < \varepsilon(\omega) < 0$. The inset shows the electric and magnetic fields in a TM-polarized mode.

$$\frac{\varepsilon(\omega)}{\sqrt{k_{\parallel}^2 - \omega^2 \varepsilon(\omega)/c^2}} = -\frac{\varepsilon_{\text{out}}}{\sqrt{k_{\parallel}^2 - \omega^2 \varepsilon_{\text{out}}/c^2}} \quad (10)$$

Assuming that, as usual, $\varepsilon_{\text{out}} > 0$, the dispersion equation of surface polaritons can be satisfied only if $\varepsilon(\omega) < 0$. The dispersion equation (10) can be rewritten in a more convenient form:

$$k_{\parallel}^2 = \frac{\omega^2}{c^2} \frac{\varepsilon(\omega) \varepsilon_{\text{out}}}{\varepsilon(\omega) + \varepsilon_{\text{out}}} \quad (11)$$

From here it is seen that the interval of the frequencies where surface polaritons can exist is narrower than $\omega_t < \omega < \omega_b$, since for real $k_{\parallel}$ the negative dielectric permittivity $\varepsilon(\omega)$ must necessarily be less than $-\varepsilon_{\text{out}}$. Let ω_s denote the upper boundary of the surface polaritons frequency range: $\varepsilon(\omega_s) = -\varepsilon_{\text{out}}$. When ε_{out} approaches ε_b , $\omega_s \rightarrow \omega_b$. For a dielectric material, the function $\varepsilon(\omega)$ is given by (4); its graph is shown in Fig. 3, and the frequency interval where a surface polariton exists is highlighted. For a metal, when $\varepsilon(\omega) = 1 - \omega_p^2/\omega^2$ (ω_p is the plasma frequency), surface plasmon–polariton exists for $0 < \omega < \omega_p/\sqrt{1 + \varepsilon_{\text{out}}}$. Fig. 4A shows surface polaritons neglecting the effects of spatial dispersion (thick magenta line marked as SP). The blue dashed lines $\omega = ck_{\parallel}/\sqrt{\varepsilon_{\text{out}}}$ and $\omega = ck_{\parallel}/\sqrt{\varepsilon_b}$ show, respectively, the photonic modes in the adjacent half-space and in the crystal (propagating parallel to the crystal surface), and the thick red lines marked as LP and UP are bulk polariton dispersion curves, shown here for reference. The photonic and bulk polaritonic dispersions do not intersect with the dispersion curve of the surface polariton, hence surface polaritons cannot be excited by an incident photon (or, once excited, cannot transform into bulk polaritons or leave the crystal as photons) – the laws of conservation of energy and wave vector cannot be simultaneously satisfied for such processes. To excite surface polaritons, one has to make use of a prism (attenuated total-reflection technique) or a grating on the crystal surface. Surface polaritons were seen as dips in the total reflection of TM-polarized light in many such experiments.

If spatial dispersion is taken into account, the spectrum becomes more complicated, since then (assuming a positive effective mass m_t) the large-wave-vector lower ‘bulk’ polariton becomes resonant with the small-wave-vector surface polariton (see Fig. 4B). As discussed above, it requires introduction of ABCs, which mix surface polaritons with bulk lower polaritons. The mixing leads to leakage of the energy of the surface wave into the interior of the crystal, providing a new (nonradiative and nondissipative) damping mechanism for surface polaritons.

Surface polaritons in more complex geometry

The presence of a surface transition layer can essentially alter the dispersion of surface polaritons. The transition layer may be either natural or artificial (a thin film on a substrate). As shown by Agranovich and Mal’shukov (1974), if an oscillation in the layer is resonant with the surface polariton, a gap with a magnitude Δ_s opens in the surface polariton spectrum. This is similar to what happens to bulk electromagnetic waves near the resonance frequency with the difference that both the excitation in the layer and the surface electromagnetic wave have a two-dimensional character. While usually the effects of a thin layer are of the order of $d/\lambda \ll 1$ (d is the layer thickness, λ is the wavelength of the light), here $k_{\parallel}^2 = \frac{\omega^2}{c^2} \frac{\varepsilon(\omega) \varepsilon_{\text{out}}}{\varepsilon(\omega) + \varepsilon_{\text{out}}}$, and therefore the gap was observed in a number of experiments, both in the infrared spectral region and in the spectral region of electronic transitions.

Surface texture, either controllable (a grating) or natural (surface roughness), as well as imperfections of the crystal that supports surface polariton (such as polycrystalline grains) alter the dispersion of surface polaritons in significant ways. As is typical for disordered samples, the surface polariton frequency acquires a shift, which results in the change of the polariton’s group velocity. Furthermore, the mode is attenuated while propagating along the surface, due to its interaction with surface imperfections (for

Fig. 4 Dispersion of surface polariton (magenta solid line) at an interface between a resonant isotropic crystal with dielectric function $\varepsilon(\omega)$ and an isotropic material with a dielectric constant ε_{out} (A) without and (B) with spatial dispersion. Thick red lines show the dispersions of bulk polaritons, and thin dashed lines show the dispersion of the photons outside the crystal and of the ‘bare’ photon in the crystal. UP, LP, and SP denote, respectively, the upper, lower, and the surface polariton branches.

rough surfaces) or scattering at the grains' boundaries (for polycrystals). Finally, while still being predominantly localized near the interface, the mode can acquire a radiative component, and hence a finite radiative lifetime. In other words, the imperfections scatter a surface polariton wave into other surface polariton modes and into vacuum radiation.

Polaritons in nanostructures with reduced dimensionality

In bulk crystals the interaction of excitons with an electromagnetic field does not give rise to radiative decay of the exciton. Instead, the energy oscillates back and forth between exciton and photon states (vacuum Rabi oscillations). This can be attributed to the conservation of total wave vector of bare excitations: An exciton with a given wave vector interacts with only one photon with the same wave vector, and there is no density of states for irreversible radiative decay.

Another situation occurs in a confined geometry, i.e. in two- (2D) and one-dimensional (1D) crystals, where an exciton has less degrees of freedom than a photon. As noted by [Agranovich and Dubovsky \(1966\)](#), in such crystals the radiative decay is restored, since in these cases only two (in 2D) or one (in 1D) of the components of the total wave vector are conserved.

Consider polaritonic effects in quasi-2D quantum wells and quasi-1D quantum wires. The translational symmetry is preserved (and, consequently, the wave vector $k_{||}$ of the exciton is a good quantum number) only in the plane of the quantum well in the first case, and only along the quantum wire in the second case. The component of the total wave vector perpendicular to $k_{||}$ is denoted by $k_{\perp}$. Photons are 3D, as before.

It turns out that the system supports two distinct kinds of states. Consider first the states with small values of the wave vector $k_{||} < k_0 \equiv \omega\sqrt{\epsilon_b}/c$. They are degenerate with photons and hence can decay into them. One can regard it as a coupling of an exciton with a wave vector $k_{||}$ with a reservoir of photons with the same component $k_{||}$ parallel to the quantum well or the quantum wire, but with all possible values of $k_{\perp}$. These photons act as a dissipative bath, and instead of forming stable hybrid states similar to polaritons in the bulk, the exciton decays irreversibly.

The corresponding radiative lifetimes can be calculated treating exciton–light coupling as a perturbation. For Frenkel exciton–polaritons, the decay times in 1D and 2D are $\tau_{1D}^{(f)} = (2\pi a/\lambda)\tau_0$ and $\tau_{2D}^{(f)} = (2\pi a/\lambda)^2\tau_0$, where $\sim$: $\tau_0 \sim 10^{-9} - 10^{-8}$ s is the radiative lifetime of the excitation of an isolated molecule, and a is the lattice constant (i.e., the radiative decay is enhanced proportionally to the number of molecules within the wavelength of light, λ). The radiative lifetime of exciton–polaritons in 2D is then $\sim 10^{-12}$ s, and such a ‘superradiant decay’ was observed in anthracene. For Wannier–Mott exciton–polaritons, the lifetime of 2D exciton–polariton for $k_{||} = 0$ was found to be $\tau_{2D}^{(WM)} = m_1 c \sqrt{\epsilon_b} / (2\pi e^2 f_{osc})$ and is about 10 ps for the parameter of GaAs. The account of the effects of thermalization and disorder-induced partial localization of polaritons considerably complicates the picture both in 1D and 2D cases.

For $k_{||} > k_0$, the modes are nonradiative. In quantum wells, to some extent, they are similar to surface polaritons, since the electromagnetic field in them decays exponentially outside of the quantum well plane. Similarly, the propagating modes can be excited using a prism or a surface grating. Radiative polaritons with $k_{||} < k_0$ can be excited directly by incident light and were observed in many semiconductor nanostructures in absorption, photoluminescence, and reflectivity spectra.

Cavity polaritons

In nanostructures called optical planar microcavities both excitons and photons have a 2D character. The interaction between them leads to formation of states similar to bulk polaritons known as ‘cavity polaritons.’ These states are stable in the sense that an exciton with a given 2D wave vector $k_{||}$ interacts with only one cavity photon with the same $k_{||}$, and, similarly to bulk polaritons, the energy oscillates back and forth between these states. In other words, in contrast to the low-dimensional nanostructures described in the previous section, where photons were 3D and the material excitons had a reduced dimension, in a planar microcavity there is no density of states for irreversible radiative decay of the exciton. After several oscillations, however, photons escape the cavity due to a finite transmission of the cavity mirrors. Cavity polaritons were observed for the first time by [Wesbuch et al. \(1992\)](#) in a GaAs planar microcavity.

An optical microcavity modifies the photonic density of states and reduces its quantization volume. As a result of confinement both the binding energy of the Wannier–Mott exciton and the exciton–light coupling are enhanced, so that Wannier–Mott exciton–polaritons are considerably more stable in the 2D geometry than in the bulk, and the polariton splitting 2Δ is much more pronounced. Furthermore, lower polaritons have a finite (rather than zero) energy at $k_{||} = 0$, and this lowest-energy state may, in principle, work as a ‘trap’ when polaritons undergo phonon-assisted relaxation after non-resonant excitation.

Since the mirrors of planar microcavities are often fabricated as distributed Bragg reflectors, a detailed description of cavity polaritons requires simulating a multi-layered structure. The dispersion equation of cavity polaritons can be obtained from Maxwell's equations with the help of the transfer-matrix method, which relates the transmission and reflectance at each interface of the multiple layers. Near the resonance, one obtains the dispersion equation of the type (7) with solutions similar to (8), with the energies of ‘bare’ exciton and photon dependent on the in-plane wave vector $k_{||}$. A significant difference arises for the cavity photon dispersion, since the perpendicular component of its total wave vector is fixed by the boundary conditions at the microcavity mirrors, leading to parabolic (for small $k_{||}$) dispersion of the cavity photon, which, in a simplifying assumption of ideal mirrors, reads:

Fig. 5 Dispersion of cavity polaritons (red solid lines) for zero detuning, i.e., when $\omega_c = \omega_t$. Blue dashed lines correspond to the dispersions of ‘bare’ cavity photon and ‘bare’ exciton. The inset shows the dependence on the wave vector of the exciton and photon weight coefficients $|C_{\text{exc}}^{(L)}(k_{||})|^2$ and $|C_{\text{phot}}^{(L)}(k_{||})|^2$ defined in Eq. (2) for the lower branch.

$$\omega_{\text{phot}}(k) = \omega_c + \frac{\hbar k^2}{2\mu} \quad (12)$$

where $\omega_c \equiv \omega_{\text{phot}}(0) = \pi c / (L_c \sqrt{\epsilon_b})$, L_c is the microcavity thickness, and $\mu = \pi \hbar \sqrt{\epsilon_b} / (c L_c)$ is its effective mass, which is very small ($\sim 10^{-5} m_e$, m_e is the electron mass). The dispersion curves of cavity polaritons are plotted in Fig. 5.

The detuning between the cavity photon and quantum-well exciton $u = \omega_c - \omega_t$ determines the ratio between exciton and photon weights in the polaritonic states for each $k_{||}$. Since this ratio determines the properties of the polaritonic states (including their ability to interact with each other and disorder), the detuning serves as a control parameter in designing polaritonic properties. The value of detuning is determined by the cavity thickness and, due to a wedge-shaped microcavity profile, can be varied in experiments.

At moderate excitation powers, the relaxation of polaritons into the ground state $\omega_L(0)$ is impeded due to the so-called bottleneck effect observed in photoluminescence experiments. Polaritons accumulate near the ‘knee’ at the lower polariton dispersion curve just below the exciton energy (near the point A in Fig. 5), since there the acoustic phonon-assisted relaxation is not effective due to an abrupt decrease of the density of final states. Qualitatively, at this point lower-branch polaritons change their character from exciton-like to photon-like, which essentially impedes the phonon-assisted relaxation (Tassone et al., 1997).

Macroscopic population of excitations in $\omega_L(0)$ state can be reached exploiting the bosonic nature of cavity polaritons. Bosonic effects had first manifested themselves in the experiments on stimulated scattering of cavity polaritons in a GaAs/AlGaAs microcavity (Savvidis et al., 2000). In these experiments, lower-branch polaritons were excited resonantly near the inflection point of their dispersion curve (point B in Fig. 5). A convex–concave character of the dispersion curve at this point allows for the polariton–polariton scattering process, when one polariton is scattered into the state with $k_{||} = 0$ (‘signal’), and one is scattered to a higher-energy state (‘idler’). A weak stimulation of $k_{||} = 0$ state by a probe beam leads to a giant (~ 100 -fold) amplification of the ‘signal’ due to the fact that the scattering rate of bosons is proportional to $n_i(1 + n_f)$, where n_i and n_f denote, respectively, the populations of the initial and final states. Several years later, Kasprzak et al. (2006) experimentally demonstrated Bose–Einstein condensation (BEC) of polaritons in a CdTe/CdMgTe microcavity. Above a threshold excitation density, the observed broad emission from a non-resonantly pumped microcavity transformed to a narrow peak centered at $k_{||} = 0$. This was accompanied by spontaneous build-up of coherent polarization of the condensed polaritons out of depolarized population below the threshold. The polariton occupancy followed Maxwell-Boltzmann distribution with the effective temperature as high as 19 K.

Since then, condensation of cavity polaritons and the polariton lasing were demonstrated by other groups in a variety of settings. The materials with larger oscillator strength, such as GaN (Christopoulos et al., 2007), ZnO (Li et al., 2013), organic materials (Kena-Cohen and Forrest, 2010) and mono-atomic layers of transition metal dichalcogenides (TMDCs; Waldherr et al., 2018) allowed for achieving room-temperature polariton lasing. For practical purposes, polaritonic laser requires not only room temperature operation, but also electrical injection of carriers. Research in this direction is underway.

The unprecedentedly high-temperature polaritonic BEC owes to small (compared to atoms) effective mass of cavity polaritons. However, polaritonic BEC differs in many ways from text-book BEC of bosonic particles. Many efforts are done to understand polaritonic BEC in presence of such factors as a finite lifetime of polaritons within the cavity, external pumping, strong polariton-polariton interactions, disorder, polarization degree of freedom, and vibronic excitations (in organic materials). Various scenarios are possible. Generally speaking, two-dimension character of polaritons implies that polaritons undergo Berezinskii-Kosterlitz-Thouless (BKT) phase transition, rather than “true” Bose–Einstein condensation. This had been confirmed experimentally by Roumpos et al. (2012), by measuring the first order spatial correlation function of polaritons, which showed typical for BKT superfluid phase power-law decay, however modified by the non-equilibrium character of the polariton condensate: Polaritons undergo decay and reappear via pumping, instead of reaching thermalization in a closed system. At the same time, structural disorder combined with driven-dissipative nature of the polariton condensate may lead to appearance of pinned vortices (Lagoudakis et al., 2008) – which are different from vortices formed spontaneously as a result of thermal fluctuations in BKT transition to a superfluid phase. This direction was further explored by Sanvitto et al. (2011), who demonstrated experimentally

and modelled theoretically all-optical control of motion of vortices and formation of controllable vortex-antivortex pairs in an optical potential, which played the role of artificial disorder. Quite recently, polaritonic condensation served as a basis for realization of an exciton-polariton topological insulator (Klembt et al., 2018). Polaritonic condensate was also suggested as a candidate system for high-temperature superconductivity (Laussy et al., 2010).

Yet another direction of research under the umbrella of cavity polaritons is currently gaining momentum. It is often called ‘molecular polaritons,’ and it studies ensembles of molecules strongly coupled to optical cavity vacuum or to surface plasmons. These systems exploit rich level structure of the molecules, with large oscillator strength of some transitions giving rise to strong and even ultrastrong coupling (both for electronic and for dipole-active vibronic transitions), and with a multitude of dark or weakly coupled to light states that take part in the relaxation dynamics of excitations. In particular, organic molecules are responsible for the observation of room-temperature single-molecule strong coupling in plasmonic nanocavities, which are made of gold nanoparticles separated by a sub-nm spacer from a gold substrate (Chikkaraddy et al., 2016). Furthermore, a pioneering observation of a cavity-induced slowing of photoisomerization rate of a photochrome by Hutchison et al. (2012) gave rise to a rapidly evolving direction conventionally referred to as ‘polariton chemistry.’ The key idea is that the strong coupling modifies the level structure of molecules, and hence the energy landscapes governing reactions pathways. As a result, a cavity-embedded molecule under properly chosen resonance conditions may exhibit a different (with respect to a cavity-free scenario) chemical properties (such as isomerization and reactivity), as well as different energy transfer ability.

Dark-state polaritons in atomic gases

Nowadays many efforts are devoted to creating techniques for controllable and reversible trapping of photonic states into atomic degrees of freedom. Photons are perfect carriers of information, while the atomic subsystem may act as a storage facility and simultaneously provide interactions between stored photons. Therefore, possible applications in quantum information and optical communication.

Recent experiments demonstrated photon trapping in coherently driven atomic gases, first in an ultracold gas, and soon after in warm alkali vapors. The generic scheme involves two electric fields (‘probe’ and ‘control’) and three atomic levels (which we denote by $|g_1\rangle$, $|g_2\rangle$ and $|e\rangle$; the first two are long-lived low-energy states, the third is an excited state of the atom). Strong control field, which resonantly couples the states $|g_2\rangle$ and $|e\rangle$, dramatically modifies the propagation of a weak probe field in a narrow spectral window near the frequency of the $|g_1\rangle \rightarrow |e\rangle$ transition. The refractive index of the gas experienced by the probe has a zero imaginary part at the resonance, and hence the probe propagates without absorption, owing to which this phenomenon is known as ‘electromagnetically induced transparency.’ In addition, near the resonance the real part of the refractive index exhibits strong variation as a function of frequency, and hence the group velocity of the probe is strongly modified. The group velocity of the probe appears to be

$$v_g = \frac{c}{(1 + \Delta^2/\Omega_c^2)} \quad (13)$$

where $\Omega_c = E_c d_{|g_2\rangle \rightarrow |e\rangle} / \hbar$ is the Rabi frequency of the control field with the amplitude E_c driving the transition $|g_2\rangle \rightarrow |e\rangle$, and Δ is, as before, the vacuum Rabi frequency of the $|g_1\rangle \rightarrow |e\rangle$ transition.

The expression (13) shows that the group velocity of the probe can be modified by varying the intensity of the control field. Decreasing E_c results in slowing the probe down to velocities as small as several meters per second (‘slow light’), or even brings a light pulse to a full stop. When $E_c = 0$ (control beam is turned off), v_g vanishes, and the photon is trapped in the atomic gas. The trapped photon is retrieved by turning the control laser on again. The storage is completely coherent as long as the entire process is adiabatic.

These dynamics happen because inside the gas the probe light is strongly coupled to the collective excitation of the atomic ensemble driven by the control field. The result of this coupling is called ‘dark-state polariton.’ When E_c vanishes, the polariton is mapped onto purely atomic excitations, and the propagation stops.

Conclusion

We have discussed polaritons – excitations that form if the strength of interaction between light and a dipole-active material resonance in a solid medium exceeds existing losses and relaxation rates. Though many ‘types’ of polaritons can be distinguished (as determined by the physical nature of the resonance the light couples with), with some reservations it is correct to say that the properties of polaritons depend more on the geometry of the system than on the specifics of the resonance. This is not surprising, given that polaritons can be viewed simply as a doublet of states originating from coupling between two oscillators. The hybrid polaritonic states possess simultaneously some properties of light (higher tolerance of structural disorder, light-like propagation) and some features of material excitations (non-linear interactions, coupling with phonons). Exploring this duality is what makes polaritons unique, and polaritonic field of research attractive and flourishing.

ΔV	electrostatic potential lineup
ϵ	dielectric constant

Introduction

Semiconductor heterojunctions are built by joining, at a planar face, two semiconductors formed by different chemical elements but usually with similar lattice structure and chemical binding, as schematically indicated in Figure 1. From the simple heterojunction constituted by two thick slabs of different materials, which presents only one interface, different heterostructures can be formed – from the double heterojunction showing confinement properties for the charge carriers to the repeated heterojunctions (multiple quantum wells and superlattices) and new artificial structures based on sequences of alternating different semiconductors of varying thickness (10–1000 Å).

Semiconductor heterojunctions show peculiar electronic properties giving rise to physical phenomena of a quantum mechanical nature, some of them not possible even in any “natural” bulk material. These peculiar electronic features are determined by the spatial profile of the electronic bands, which is in turn controlled both by intrinsic characteristic of constituent semiconductors, such as lattice constants, energy gaps, doping, and extrinsic features such as chemical and structural details in the interface region, where the bands exhibit discontinuities (see Figure 2). The spatial profile of the electronic bands can be used to properly tailor the space-charge distribution and the behavior of the charge carriers both in the growth direction (transport properties) and in the potential wells parallel to the interface planes (confinement properties), giving the semiconductor heterojunctions a crucial role in modern electronic and optoelectronic devices.

The introduction of heterojunctions dates back to almost 50 years ago. Herbert Kroemer and Zhores I Alferov obtained the Nobel Prize in Physics in 2000 “for developing semiconductor heterostructures used in high-speed- and opto-electronics.” In 1957, Herbert Kroemer published the first proposal for a heterostructure transistor. His theoretical work showed that heterostructure devices could offer superior performance compared to conventional transistors. In 1963, H Kroemer and Zhores I Alferov

Figure 1 Stick-and-ball model of an abrupt semiconductor heterojunction between two zinc blende semiconductors with no-common ions. The interface is (0 0 1) oriented. (Adapted from Sorba L, *et al.* (1992) Structure and local dipole of Si interface layers in AlAs–GaAs heterostructures. *Physical Review B* 46: 6834.)

Figure 2 Schematic spatial profile of the valence and conduction bands along the growth direction for a semiconductor heterojunction, with band bending due to space-charge effects and definition of band offsets, VBO and CBO.

independently proposed ideas to build semiconductor lasers from heterostructure devices, using a double heterostructure to confine carriers. Alferov built the first semiconductor laser from gallium arsenide and aluminum arsenide in 1969.

The traditional semiconductor heterojunctions involve elements of the central portion of the periodic table, starting from Si and GaAs. Si- and GaAs-based technology is the most mature, but many other III–V and II–VI binary compounds as well as alloys are used nowadays, the choice depending on the particular application. Among alloys, perhaps the most widely studied and used is $\text{Al}_x\text{Ga}_{1-x}\text{As}$, in particular, in its interface with GaAs.

High-quality semiconductor interfaces are easily built from two semiconductors which are isovalent and lattice-matched, but more generally they can be also heterovalent (involving semiconductors of different groups) and lattice-mismatched, with slightly different lattice parameters. With the addition of nitrides of II(IV)–VI compounds and of magnetic semiconductors to the most conventional ones, the range of the lattice constants and of the energy gaps which is covered by the different constituents used to form heterostructures is very large, as indicated by Figure 3, suggesting possibilities for new fundamental physics and device applications.

Thanks to the improvement of experimental techniques such as molecular beam epitaxy (MBE) and metal–organic chemical–vapor deposition (MOCVD), it is possible to grow high-quality pseudomorphic heterostructures without misfit dislocations or other defects, also with semiconductors with a rather small lattice mismatch (i.e., less than a few percent), and with different but almost commensurate structures.

A heterojunction indicated with A/B typically corresponds to a particular growth order: B is the substrate and A the epilayer. Another specific feature that is usually indicated is the crystallographic growth axis, which determines the interface plane.

Figure 3 Energy gaps vs. lattice constants for various IV (stars), III–V (closed circles), II(IV)–VI (open squares) zinc blende semiconductors. The visible electromagnetic spectrum is also indicated.

Electronic Properties: Band Alignments

The spatial profile of the electronic bands is mostly determined by the band discontinuities at the interface. The bandgap difference ΔE_g , normally existing between the constituent materials, is shared among valence and conduction bands, thus giving rise to the valence and conduction band offsets (VBO and CBO):

$$\Delta E_g = \text{VBO} + \text{CBO} \quad [1]$$

There are different types of band lineups which are possible, schematically indicated in Figure 4. The straddling or type-I lineup characterizes, for instance, the GaAs/Ga_xAl_{1-x}As interface. Modern optoelectronic devices – including quantum well lasers – are based on such a lineup, typically with a double or repeated heterojunction, where the charge carriers are both confined in the slab of material with the lowest energy gap (see Figure 5). Other types of lineups are the staggered or type-II and the broken-gap or type-II-misaligned lineups, which could be preferred for some specific applications.

Extensive theoretical and experimental work has targeted the problem of band alignments since a long time. In particular, an important and general issue widely debated is whether the band discontinuities are essentially determined by the bulk properties of the constituents, or if some interface-specific phenomena, such as crystallographic orientation and abruptness, may affect them in a significant way. A large joint experimental and theoretical/computational effort has been performed to finally clarify, quite recently, the physical mechanisms which give rise to the band alignment. Several books and review articles are available on the subject, as indicated in the “Further reading” section. Some of them are focused on the problem of band offset engineering, that is, on the possibility of controlling the interfaces thus providing a way to manipulate the band lineups and tune the transport properties across the junctions.

Measuring Band Offsets

Several experimental techniques are available for measuring energy band discontinuities, including optical and transport measurements. Since the late 1970s, spectroscopic techniques have emerged as a fundamental tool for investigating heterojunctions on a microscopic scale. In photoemission spectroscopy, for instance, a direct measurement of the band discontinuities can be done by comparing specific core-level binding energies E_{cl} with respect to valence band top edges E_v in bulk samples with those from the heterostructure:

$$\text{VBO} = [E_{cl}(\text{Ga } 3d) - E_v(\text{Ga As})] - [E_{cl}(\text{Al } 2p) - E_v(\text{Al As})] + \Delta E_{cl} \quad [2]$$

An example is schematically shown in Figure 6 for the AlAs/GaAs(001) interface.

Figure 4 Schematic possible types of band alignments: (a) straddling, (b) staggered, and (c) broken gap. Flat bands are represented, as the focus is on a region which is of the order of 10 atomic units, and the band bending is negligible at this scale.

Figure 5 Confinement of electrons and holes in the slab of a material with the lower gap in a double semiconductor heterostructure with straddling-type band alignment.

Figure 6 Example of a photoemission measurement of the band offset at the semiconductor heterojunction AlAs/GaAs(001). Core-level binding energy distribution curves for Al 2p and Ga 3d states referred to the corresponding AlAs and GaAs valence band top edges are schematically drawn. The zero of the energy scale is arbitrarily taken at the center of the Ga 3d emission peak. The variation of the separation ΔE_{cl} of the core level peaks from the case of the two bulks, considering the topmost valence bands of the two materials aligned (a) and the heterojunction (b) is a direct measurement of the VBO.

Predicting Band Offsets

Theoretical and numerical investigations based on different approaches have contributed toward predicting band offset values and identifying the basic mechanism responsible for band offsets. These investigations can be divided mainly into two classes: (1) models and approaches making simplifying and sometimes drastic approximations in describing the interface, but retaining important physical concepts, and (2) accurate computational predictions based on fully self-consistent *ab initio* approaches, which allow one to fully take into account the interface details, such as orientation, abruptness, and defects.

In general, no universal energy scale exists on which the band structures of the different semiconductors can be easily and uniquely referred, but simple and old models based on intrinsic reference levels have been widely used and have given successful predictions for a number of heterostructures: from the oldest models by Anderson, Frensley, and Kroemer, based on the difference between the electron affinities of the two semiconductors and the concept of charge neutrality levels, to Tersoff's model emphasizing the role of interface dipoles. More refined quantum mechanical approaches, based on the envelope function concept or using the tight-binding method have also been widely and successfully applied. They are reviewed in the books cited above.

The second class of theoretical/computational investigations, more recent, includes *ab initio* approaches, which are based on the solution of quantum mechanical equations for the system under consideration without any use of empirical parameters. This seemingly unaffordable task has been made feasible, thanks to the density-functional theory (DFT) proposed by Walter Kohn, who received the Nobel Prize in Chemistry in 1998 for the same, and for its approximations for practical applications, such as the local-density approximation. DFT has proven to yield reliable results, at an acceptable computational cost, on the electronic ground-state properties of complex crystalline systems, allowing a meaningful comparison with experiment or even accurate predictions of quantities not yet accessible experimentally, with an extremely useful predictive power.

In *ab initio* approaches, semiconductor heterostructures are normally modeled using periodically repeated supercells with a limited number of atoms. The relevant effects due to the presence of the interface are confined in a small region, and the bulk features of the charge density distribution and electrostatic potential are completely recovered within a few atomic units from the interface. This justifies the concept of abrupt discontinuities of the electronic bands across the interfaces which is used in the schematic diagrams of electronic band profiles.

The supercell self-consistent calculations provide the electronic charge density distribution and the corresponding electrostatic potential, as shown in Figure 7. Filtering out the microscopic oscillations with the bulk-like periodicity, one can unambiguously define an "interface dipole" and extract a potential difference across the interface, ΔV , which, in principle, depends on the interface structural

Figure 7 Contour plot of the valence electron density distribution (a) for GaAs/AlAs(001) heterojunction over a (110) plane containing the growth axis and centered on the interface anion. Profiles of the electron density and of the electrostatic potential along the growth direction averaged over planes parallel to the interface ($\bar{n}(z)$ and $\bar{V}(z)$) (b), and further averaged along the growth direction with a filter equal to the periodicity of bulks ($\bar{n}(z)$ and $\bar{V}(z)$) (c).

and chemical details. The final band offsets VBO and CBO are determined by the difference ΔE_v and ΔE_c between the relevant band edges in the two materials, measured with respect to the average electrostatic potential in the corresponding bulk crystals:

$$\text{VBO} = \Delta V + \Delta E_v \quad [3]$$

$$\text{CBO} = \Delta V + \Delta E_c \quad [4]$$

When the two semiconductors constituting the heterostructure are rather similar (in structure and chemical composition), their differences can be quite minute with respect to the typical bulk variations, and a low-order perturbation approach is appropriate.

The state-of-the-art theoretical approaches allow one not only to compute band discontinuities accurately but also to obtain an insight into the atomic-scale mechanisms which determine the band lineups, and interpret and predict their trends. However, the predictive capability of theoretical schemes is actually limited by the difficulty in predicting the actual atomic-scale arrangement at the interfaces, and their kinetic versus thermodynamic character.

Band Offset Trends

Some peculiar trends in band offsets at semiconductor heterojunctions have been clarified, thanks to the large joint experimental and computational effort: at lattice-matched isovalent heterojunctions, the band offsets depend only on the bulk properties of the two materials, whereas at heterovalent heterojunctions they crucially depend on the interface orientation and other microscopic details. These results are briefly reviewed and justified in the following section.

Lattice-Matched Semiconductor Interfaces

Isovalent semiconductor heterojunctions

The GaAs/AlAs heterojunction is the simplest prototype of lattice-matched common-anion heterojunctions. The different cations are isovalent; therefore, the induced potential drop across the interface is only due to the electronic charge. Measurements and accurate numerical investigations show that the VBO and CBO are independent of the interface orientation and abruptness. These results can also be generalized to isovalent no-common-ion heterojunctions such as InAs/GaSb and InP/Ga_{0.47}In_{0.53}As, where the lattice-matching conditions result from a balance between the differences of the cationic and anionic core radii, and consequently an important microscopic and configuration-dependent interfacial strain may establish.

Consequences of the bulk-like character of the VBO and CBO are the commutativity and transitivity relationships, which are valid, at least approximately, in the whole class of isovalent semiconductor heterojunctions:

$$\text{VBO}(A/B) = -\text{VBO}(B/A) \quad [5]$$

$$\text{VBO}(A/B) = \text{VBO}(A/C) + \text{VBO}(C/B) \quad [6]$$

Heterovalent semiconductor heterojunctions

For the sake of clarity, the reader is referred to the case of Ge/GaAs as the simplest prototype of heterovalent semiconductor heterojunctions, but similar considerations apply to other heterojunctions characterized by a valence mismatch between the constituent atoms, such as those among ZnSe, Ge, and GaAs.

In the (1 1 0) direction, each atomic plane is characterized by the same average ionic charge, so that an abrupt junction does not carry ionic charge contribution and the lineup is due only to the electrons. At variance, ideally abrupt interfaces along a polar direction such as (0 0 1) would be charged and hence thermodynamically unstable, as already emphasized first by Harrison in 1978. The simplest neutral and stable interfaces one can envision are terminated by one mixed plane of anions or cations, As_{0.5}Ge_{0.5} or Ga_{0.5}Ge_{0.5} (see Figure 8). These two interfaces are stoichiometrically inequivalent, and, because of ionic point charges contribution due to the different valence of the atoms involved (Ge vs. Ga, Ge vs. As), they also correspond to different band offsets. Elementary electrostatics together with a linear response theory predict that the screened ionic point-charge contribution to the offsets is equal in magnitude and opposite in sign for the two interfaces: $\Delta V_{\text{ionic}} = \pm \pi e^2 / 2a_0 \langle \epsilon \rangle$, where a_0 is the lattice parameter involved and $\langle \epsilon \rangle$ a proper average of the dielectric constants of the constituents. The maximum predicted possible variation with interface composition of the band offset at these interfaces is thus $\pi e^2 / a_0 \langle \epsilon \rangle \approx 0.8 \text{ eV}$ for Ge/GaAs. For ZnSe/Ge, where the valence difference between the constituting elements is twice, the maximum possible variation would be $2\pi e^2 / a_0 \langle \epsilon \rangle \approx 1.3 \text{ eV}$.

In general, the atomic interdiffusion which may also occur across the interface over several atomic planes, depending on the growth conditions, reduces the point-charge contribution to the offset, and the observed variations of the offsets are smaller. However, for heterovalent heterostructures deviations from the commutativity and transitivity rule definitely beyond the experimental resolution, up to $\approx 0.5 \text{ eV}$, are observed, and these are a clear fingerprint of the formation of inequivalent interfaces.

Figure 8 Atomic configurations for the two simplest neutral Ge/GaAs interfaces (a), (b), and for a Ge bilayer embedded in GaAs (c). (Adapted from Sorba L. *et al.* (1992) *Physical Review B* 46: 6834.)

Lattice-Mismatched Semiconductor Interfaces

In lattice-mismatched heterojunctions, the band offsets are affected by the stress state of the two materials, depending on the substrate. In pseudomorphically grown heterostructures, the epilayer accommodates its mismatch with the substrate with an almost homogeneous strain and a lattice constant $a_{\perp}$ along the growth direction, which essentially depends on its elastic properties and on the mismatch with the substrate. The strain state of the epilayer affects the band edges with a combined effect of shift and split. The former affects the averages of the band edge manifolds, calculated with respect to the reference electrostatic potential, and depends on the hydrostatic component of the strain, that is, on the relative volume change with respect to the cubic unstrained material. Splitting effects depend on the orientation and sign of the strain (tensile or compressive). The total variation of the VBO with strain also includes the variation of the electrostatic potential lineup ΔV .

The simplest case of lattice-mismatched heterojunctions is Si/Ge, which is an example of isovalent homopolar interfaces. The predicted variation of the VBO at this heterojunction is ~ 0.5 eV, changing the substrate from Si to Ge. Larger effects could be, in principle, possible at heterovalent lattice-mismatched heterojunctions, such as Si/GaAs, or in presence of larger lattice mismatches. However, the difficulty of growing high-quality lattice-mismatched heterojunctions drastically limits their formation and their use in practice.

Band Offset Engineering

In bulk semiconductor technology, one of the most important and widely used features has been the possibility of intentionally varying the electronic properties by alloying and doping. For semiconductor heterojunctions, a similarly important challenge is to control and artificially modify the band offsets.

As already mentioned, the VBO and CBO at lattice-matched isovalent semiconductor heterojunctions are mostly determined by the bulk properties of the constituents, and interface details such as orientation and stoichiometry play a very minor role, whereas at heterovalent heterojunctions they are very sensitive to these extrinsic features. As a consequence, heterovalent heterojunctions seem to be ideal candidates as tunable heterojunctions, while using only isovalent materials, it seems that the only way to tune the offset is to act on their bulk properties with strain or with alloying.

Actually, the peculiarity of heterovalent interfaces leads naturally to a practical way for modifying the offset also at isovalent heterojunctions, or even for creating an offset at a homojunction. For instance, joining together the two inequivalent interfaces Ge/GaAs(001) (Ge–As and Ge–Ga terminated), one has the following sequence of atomic planes: ... As–Ga–As–Ge_{0.5}Ga_{0.5}–Ge_{0.5}As_{0.5}–Ga–As–Ga... Therefore, using the difference between the VBOs of these two inequivalent interfaces, a net potential drop $\Delta V = \pi e^2 / a_0 \langle \epsilon \rangle$ is predicted across the mixed bilayer. This potential drop is the same that would result from a microscopic capacitor whose plates are placed at a distance $a_0/4$, and carry a surface charge $\sigma = e/a_0^2$. The above sequence of atomic planes can also be thought of as due to the transfer of a proton per atomic pair from the As to the Ga planes.

This viewpoint is easily generalized to arbitrary concentrations of Ge in a pair of consecutive compensated GaAs planes, Ge_xGa_{1-x} and Ge_xAs_{1-x}, to ensure local charge neutrality. The maximum potential drop would be, in principle, $\Delta V_{\max} = 2\pi e^2 / a_0 \langle \epsilon \rangle$ for the case $x = 1$, that is, for an entire Ge bilayer embedded (see Figure 8). The above results can be further generalized to the heterojunctions, for example, doping a GaAs/AlAs interface with ultrathin layers of Si or Ge. In this case, the

interlayer contribution can reduce or increase the intrinsic VBO according to the growth sequence. These predictions have been indeed experimentally confirmed for Si interlayers at GaAs/AlAs and AlAs/GaAs (0 0 1) junctions and analogous effects have also been observed in other systems.

Localized Interface States

Another important issue in the heterojunction electronic structure concerns the presence of localized interface states in heterojunctions, their origin, and their role in determining the electronic characteristics of the junctions. The existence of localized interface states is generally claimed whenever anomalous features are observed in photoemission, optical, or transport measurements. Their unambiguous identification, however, is a difficult task in experiments. Reflectance anisotropy spectroscopy has been recently applied to a few interfaces and seems to be a promising tool for more direct investigations.

The electronic states of a heterojunction can be extended everywhere, localized in one material or the other (acting as a quantum well), or localized at the interface. The true interface states are not degenerate with bulk Bloch states, decay exponentially away from the interface, and exist only in the mutual energy gaps. The comparison of the band structures of the two bulk materials with the spectrum of the heterojunction allows one to identify those states which do not belong to the bulk band structures, and are, therefore, candidates to be interface states. Localized electronic states can be successfully identified in numerical investigations also by the local density of states: far from the interface on the two sides of the junction, it yields the bulk densities of states of the two materials, whereas its deviations with respect to the constituting bulk state densities in the interface region would indicate the presence of states which are localized there.

Interface states can have different physical origins. In some cases, they are associated with defects which typically arise at junctions between two morphologically different phases (e.g., cubic and wurtzite). But localized electronic states can also occur, in principle, at semiconductor heterojunctions with constituents having the same or similar structure but different chemical properties. Simple electron-counting schemes indicate that the valence mismatch between neighboring atoms from opposite sides of the junction could result in localized interface states corresponding to donor or acceptor bonds. Therefore, heterovalent heterojunctions, which exhibit such kind of bonds in the interface region, are natural candidates for the existence of localized interface states. Localized states have been experimentally detected at diamond/zinc blende interfaces, for example, Ge/ZnSe, at zinc blende/zinc blende heterovalent interfaces, for example GaAs/ZnSe, and even at isovalent no-common-ion interfaces, for example, BeTe/ZnSe.

Accurate calculations predict that interface electronic states critically depend not only on the type of heterojunction (i.e., heterovalent rather than isovalent), but on the particular atomic-scale morphology of the interface.

Semiconductor Heterostructures and Spintronics

The word "spintronics" denotes electronic-like heterostructures where the relevant physical quantity is the spin of the carriers and its interactions with external magnetic fields, rather than the charge of holes and electrons and the associated electronic properties.

Semiconductor heterostructures using carrier spin as a new degree of freedom offer new functionality with respect to conventional junctions. A large effort is currently devoted to integrate traditional III-V and II-VI semiconductors with ferromagnetic semiconductors or, more generally, with other ferromagnetic materials including metals and half-metals. There are, however, several advantages using all-semiconducting devices: interface properties, such as lattice matching and band offsets, are more understood and controllable, and the integration with the existing conventional semiconductor technology is easier. The diluted ferromagnetic semiconductors are semiconductor compounds where a fraction of the constituent ions is replaced by magnetic ions. This is the case, for instance, of (Ga,Mn)As, which has received particular attention: Mn is a heterovalent substitutional impurity for Ga in GaAs (valence II with respect to the valence III of Ga), and therefore, it can be used as a source of spin-polarized holes. An Mn content up to 5% is sufficient to make (Ga,Mn)As ferromagnetic.

Furthermore, there is the possibility of a good integration of half-metals with conventional semiconductors: these are materials that have only one occupied band at the Fermi level, and behave as a metal in one spin channel and as a semiconductor in the other. Current effort, both experimental and theoretical, is nowadays devoted to predict those particular heterostructures where half-metallicity is also maintained in the presence of the interface.

Introduction

The role of mobile charge carriers is a key factor in semiconductor device operations. These free carriers are supplied by doping semiconductors with certain kinds of impurities. The electrical properties of semiconductors can thus be controlled by adding a small amount of impurities. However, some other impurities and crystal defects often have detrimental effects on the performance of the device. These impurities and defects create discrete energy levels in the bandgap of the host semiconductor, and exert various influences (usefully or detrimentally) on the semiconductor characteristics. Therefore, a knowledge of the electronic structure of the impurities and defect states in semiconductors is very important.

Structural and Electrical Properties of Impurities and Crystal Defects

Impurity atoms normally substitute the atoms of the host semiconductor (substitutional impurity atom). However, some of them, especially those with small atomic radii, often enter the interstitial site in the host crystal lattice (interstitial impurity atom). On the other hand, the well-known point defects – the vacancies (lattice points where atoms are lacking) and the interstitials (atoms of the host semiconductor occupying the interstitial sites) – are examples of the intrinsic crystal defects. These point defects sometimes generate a complex center such as the Frenkel defect (the pair of vacancy and interstitial atoms in the neighboring lattice sites). There are two types of impurities and defects from the electrical point of view. One of them supplies free electrons and the other provides holes in the host crystal. The former is called donor and the latter, acceptor. For example, when V-column elements such as P and As are doped in Si (IV-element), one excess valence electron is easily liberated (the impurity atom is ionized) in the Si lattice even at room temperature because of the low binding energy between the electron and the impurity atom. Also, when a III-element such as B is introduced into Si, one valence electron is deficient so that one hole is created and easily released in the Si lattice at room temperature due to their very low binding energy. These impurities, having very low binding (ionization) energies are termed shallow impurities (shallow donor and shallow acceptor). If Si is doped with VI-elements (S, Se, and so on) or II-elements (Zn, Cd, and so on), two free electrons or two holes per impurity atom, respectively, are created (double donor and double acceptor). On the other hand, some impurity elements (and crystal defects) have very high binding energies so that electrons or holes are not easily liberated in the host crystal at room temperature. These impurities with high binding energies are called deep impurities. Heavy metals such as Fe, Ni, and Cu in Si, for example, are deep impurities. In compound semiconductors, the same impurity atom behaves both as a donor and an acceptor depending on its occupied site (amphoteric impurities). The Si atom in GaAs behaves as a donor if it occupies the Ga site and as an acceptor when it substitutes the As atom. When IV-elements (Ge, C, etc.) are doped in Si, they also behave as donors or acceptors although there are cases when they are not electrically active. These impurities are called isoelectronic impurities. With doping of the impurities in semiconductors, the discrete energy levels are normally generated in the bandgap of the host semiconductor. For shallow donors and acceptors, these energy levels are located very near the bottom of the conduction band and the top of the valence band, respectively. On the other hand, the energy levels for the deep impurities occur near the middle of the bandgap.

Theory of the Electronic States of the Shallow Impurities

Shallow impurities can be theoretically treated using the effective mass approximation and the hydrogen atom model. Consider the case of the donor (the acceptor can also be considered similarly). The excess electron moves in an orbit round the impurity ion due to the Coulomb interaction between them in the host crystal, just like the hydrogen atom. The Coulomb potential is much smaller than that in the hydrogen atom due to the screening effect of the valence electrons (the change of the valence electron distributions around the impurity ion) in the crystal lattice. The screened Coulomb potential is written as $U = Zq^2/\epsilon_s r$, where Z is the valence number of the impurity ion, q the electronic charge, ϵ_s the dielectric constant of the host semiconductor and, r is the distance

between the electron and impurity ion. The screening effect is effectively represented by the dielectric constant ϵ_s . Thus, the electron is very loosely bound by the impurity ion (very low binding energy) and its wave function extends in the wide range of the crystal lattice. Hence, the electron moves feeling both the periodic potential of the host crystal and the screened Coulomb potential. The effect of the periodic potential on the motion of electrons is well described in terms of the "effective mass" m^* , that is, electrons in the periodic potential of crystal behave as if they are free electrons with their mass m^* being different from that (m_0) in a vacuum. Therefore, the electrons in the orbital round the shallow impurity ions can be considered as electrons with an effective mass m^* moving in the screened Coulomb potential U . The fundamental Schrödinger equation for these electrons is written as follows:

$$\left[\left(\frac{\hbar}{2m_0} \right) \nabla^2 + (V - U) \right] \Psi(\mathbf{r}) = E \Psi(\mathbf{r})$$

Here, $\nabla^2 = (\partial^2/\partial x^2 + \partial^2/\partial y^2 + \partial^2/\partial z^2)$ is an operator, $\Psi(\mathbf{r})$ the wave function of the electron, $r = (x, y, z)$ the position vector of the electron, V and U the periodic potential in the perfect crystal and the screened Coulomb potential, respectively, and E is the energy of the electron. In the case of $U=0$ (perfect crystal), the solution of the above equation is given by the Bloch wave function $\Psi_{nk}(\mathbf{r}) = \exp(i\mathbf{k}\mathbf{r})u_{nk}(\mathbf{r})$, where $\exp(i\mathbf{k}\mathbf{r})$ is the wave function of the free electron (plane wave) extending to the whole crystal, and $u_{nk}(\mathbf{r})$ is the function having the periodicity of the crystal lattice with n and $\mathbf{k}$ being the quantum number specifying the energy bands and the wave number vector, respectively. For applying the effective mass approximation to the shallow impurity problem, the wave function $\Psi(\mathbf{r})$ is expanded by the Bloch functions or their Fourier transforms (the Wannier functions) and substituted in the equation. Thus, the following equation is obtained:

$$\left[\frac{\hbar}{2m^*} \nabla^2 - U \right] \Phi(\mathbf{r}) = E \Phi(\mathbf{r})$$

This equation is the same as that for the hydrogen atom except for the difference in the electron mass. The wave functions of the electrons are given as the product of $\Phi(\mathbf{r})$ and the function which has the periodicity of the crystal lattice. The above equation is for the case of the isotropic conduction band (in which the effective mass is the same for all crystal orientations). For example, some compound semiconductors such as GaAs and InP have this type of conduction bands. On the other hand, the conduction bands are anisotropic in semiconductors such as Si, Ge, and GaP, that is, the effective mass is different in different crystal orientations. The valence bands of most semiconductors have degeneracy in which the energies of the "heavy" holes and the "light" holes coincide at the top of the band. For these cases, the above equation should be modified to take the anisotropy or degeneracy of the band structures into consideration. The details of the same are not discussed here.

The solution of the above equation is well known for the "hydrogen atom." The electronic states of the hydrogen atom are specified by the principal (Bohr) quantum number n , the angular momentum quantum number l , the magnetic quantum number m , and the spin quantum number s . The principal quantum number n is the positive integer and the angular momentum quantum number $l \leq n-1$ for each n value. The magnetic quantum number m is given as $m = l, l-1, l-2, 0, \dots, -l-1, -l$ ($l \geq m \geq -l$) and the spin quantum number $s = \pm 1/2$. The electronic states corresponding to $l=0, 1$, and 2 are called s, p , and d states, respectively. Then the state of $n=1$ and $l=0$ is called as the $1s$ state (the ground state: the state of the lowest energy). The higher energy states (the excited states) are thus called as $2s$ ($n=2, l=0$), $2p$ ($n=2, l=1$), $3s$ ($n=3, l=0$), $3p$ ($n=3, l=1$), $3d$ ($n=3, l=2$) states and so on. The energies E_n of these states obtained from the above equation are given as

$$E_n = -E_0/n^2 \quad (n=1, 2, 3, \dots)$$

$$E_0 = (\epsilon_0/\epsilon_s)^2 (m^*/m_0) E_H$$

Here E_0 is the energy of the ground ($1s$) state and, ϵ_0 and ϵ_s are the dielectric constants of the vacuum and semiconductor respectively. E_H is given as $E_H = (1/\epsilon_0)^2 (q^4 m_0 / 2\hbar^2) = 13.6\text{eV}$ and is the ground-state energy of the real hydrogen atom (the Rydberg constant). From the above equations, it is obvious that the energy E_n is only dependent on the principal quantum number n (degenerate with respect to the other quantum numbers l, m , and s) in the case of the isotropic conduction band. For the donor and acceptor, respectively, the ionization energies (the binding energies) E_D and E_A from the ground state can be calculated as $E_D = E_C - E_0$ and $E_A = E_V - E_0$, where E_C and E_V are, respectively, the energies of the bottom of the conduction band and the top of the valence band. In Figure 1, the shallow impurity levels are schematically shown.

The wave function is $\Phi_{1s}(r)$ of the ground state is written in the following:

$$\Phi_{1s}(r) = (1/\pi)^{1/2} (1/a^*)^{3/2} \exp(-r/a^*)$$

Here, it is assumed that $z=1a^*$ is the Bohr radius given as $a^* = (\epsilon_0 m^*) (\hbar^2 / m_0 q^2)$ and represents the extent of the electronic wave function in the real crystal space. The wave function exhibits a sharp decrease at $r > a^*$. The wave functions of some excited states are as follows:

$$\Phi_{2s}(r) = (1/\pi)^{1/2} (1/2a^*)^{3/2} [2 - (r/a^*)] \exp(-r/2a^*)$$

$$\Phi_{2p}(r) = (1/\pi)^{1/2} (1/2a^*)^{3/2} (r/\sqrt{3}) \exp(-r/2a^*)$$

In these excited states, the electron wave functions show a strong decay as

$$r > 2a^*$$

Figure 1 Shallow impurity level scheme in the wave number (k) space.

Experimental Determination of the Shallow Energy Levels

The energy levels of shallow impurities can be determined accurately using the infrared absorption measurements at very low temperatures. It is well known that electrons bound to a hydrogen atom can be excited to higher energy levels by the absorption of light. Similarly, electrons captured by shallow impurity levels are transferred to higher energy levels by absorbing infrared light. These optical transitions are allowed only when the difference (Δl) in the angular momentum quantum numbers (l) between two related energy levels is 1 ($\Delta l = 1$) (the selection rule). Thus the electrons can be excited from the $1s$ (ground) state to the $2p, 3p, 4p, \dots$ (excited) states. However, the transitions $1s \rightarrow 2s, 1s \rightarrow 3s, \dots$ (and so on) are not allowed. The absorption peaks of the infrared light are very sharp because these energy levels are completely discrete. By measuring the infrared absorption spectrum at very low temperature (~ 4.2 K), one can accurately determine the energies between the ground state and many excited states. The excited levels with very large principal quantum numbers n are located very close to the conduction or valence band edge so that one can determine the ground-state ($1s$) level and any excited ($2p, 3p, \dots$) levels measured from the band edge (ionization energies). In Table 1, some examples of the measured shallow donor and acceptor levels (ionization energies) in Si are shown together with the calculated ones. The agreement between the measured and calculated values is excellent.

Theory of the Electronic States of the Deep Impurities (or Defects)

For the deep impurities, electrons (or holes) are very tightly bound to the impurity atom nucleus due to the highly localized core potential. The motion of the bound electrons (or holes) is strongly affected by this core potential and the wave functions of these carriers are also highly localized around the impurity atoms (or defect centers). Therefore, both the effective mass approximation and the hydrogen atom model cannot be applied to the deep level cases. The tight binding approximations, such as the linear combination of atomic orbitals (LCAO) method, are suitable to treat the deep-level problem. Since the core potentials are not small, the

Table 1 Some examples of the ionization energies of the ground states of shallow donors and acceptors

Host semiconductors	Impurities	Experimental value(meV)	Theoretical value(meV)
Si	P (D)	45.5	44.3
	As (D)	53.7	53.1
	Sb (D)	42.7	31.7
	B (A)	45.0	31.6
GaAs	Si (D)	5.84	5.72
	Ge (D)	5.88	5.72
InP		7.14	7.14
InSb	Te (D)	0.6	0.6

D: donor; A: acceptor.

conventional perturbation theory is not applicable and the Green-function approach is useful to solve the fundamental Schrödinger equation. The Schrödinger equation describing the motion of the electron bound to the deep impurity is given as follows:

$$(H_0 + U)\Psi(r) = E\Psi(r)$$

Here, H_0 is the Hamiltonian operator for the perfect crystal and U is the localized potential due to the deep impurity atom. In order to solve the above equation, the impurity potential U needs to be determined. However, this is very difficult for the following reason. In many cases of deep impurities, the impurity atoms are slightly displaced from the lattice point of the host semiconductor, and a microstrain is induced around the impurity atoms. It is assumed that if the impurity atom occupies the lattice point (as is the case for shallow impurities), a shallow energy level of E_D is generated. When this impurity atom is somewhat displaced from the lattice point (the lattice relaxation occurs), a deep energy level E_0 is assumed to be created. Also, a lattice relaxation energy (strain energy) E_L occurs. If $E_0 + E_L$ is higher than E_D , it is energetically stable to form the deep level with a small displacement of the impurity atom from the lattice point rather than the shallow levels. If the mixed semiconductor crystal AlGaAs is doped with Si, a deep-level center (called the DX center) is created while Si atoms act as shallow donors in GaAs. This DX center is considered to be as the above stated case. In order to determine the impurity potential U , the effect of the lattice relaxation should be taken into account exactly, which, however, is a very difficult problem. Many calculations have been performed by assuming various forms of the impurity potential U . The wave function $\Psi(r)$ is expanded in terms of the sp^3 atomic orbital functions (Φ_j) as $\Psi = \sum_j a_j \Phi_j$ (LCAO). Then the Schrödinger equation is solved using the Green-function approach under the various assumptions of the impurity potentials. However, quantitative comparisons between the calculated and observed energy levels are difficult because of the difficulty in including the lattice relaxation effect in the analysis.

There are some cases of deep levels, in which the energy level merges into the conduction or the valence band of the host semiconductor. This level is called the resonant level. The existence of this level affects the band structure of the host crystal because the density of states of the impurities are superposed to those of the conduction or the valence band. With doping of the isoelectronic impurities, this resonant level is often observed. These resonant energy levels can also be calculated using the above Green-function approach.

Experimental Determination of the Deep Energy Levels

The deep level transient spectroscopy (DLTS) is the most powerful tool to determine deep energy levels. This method is based on the measurements of the transient electrical capacitances of the metal–semiconductor (Schottky) contact as the pulsed reverse bias voltage is applied. The transient Schottky capacitance $C(t)$ is written as follows.

$$C(t) = C_\infty \left[1 - \left(\frac{N}{2} \right) \exp\left(-\frac{t}{\tau}\right) \right]$$

Here $N = N_T / (N_D + N_T)$, N_T and N_D are the density of the deep impurity and the shallow donor, respectively. $C_\infty = \{(\epsilon_s \epsilon_0 / 2)(V + V_D)(N_D - N_T)\}^{1/2}$, ϵ_s and ϵ_0 are the dielectric constant of the semiconductor and a vacuum, respectively, and V_D is the diffusion potential of the Schottky contact. The relaxation time τ can be written as $e_n = 1/\tau$, where e_n is the electron (or hole) emission coefficient of the deep impurity and given as $e_n \propto C_n \exp[-(E_C - E_T/kT)]$ because electrons (and holes) are emitted from the deep levels by thermal activation. Here, C_n is the capture cross section of the deep impurity, E_T and E_C are the deep impurity energy level and the bottom of the conduction band, respectively. T and k are the absolute temperature and the Boltzmann constant, respectively. If the transient capacitance $C(t)$ is measured as a function of temperature T , the temperature dependence of e_n is obtained. From the plot of $\ln e_n$ versus $1/T$ (the Arrhenius plot), the deep energy level E_T can be easily determined. The capture cross section C_n and the deep impurity density N_T are at the same time determined. The famous example of the deep level is the EL2 center observed in the semi-insulating GaAs single crystal which is the cause of the high resistivity. The ionization energy of this EL2 center was measured to be 0.7~0.8 eV (located near the middle of the bandgap of GaAs).

Introduction

Two conceptually different methods are used to fabricate semiconductor nanostructures. In the top–down approach, lithography is used to fabricate nanostructures. In the bottom-up approach, small nanostructures form by self-organization during epitaxial growth. The greatest advantage of the top–down approach is the large variety of different structures, which can be generated by lithographic methods. In the case of the bottom-up approach, the variety of structures is much more limited. Islands, wires, rods, and rings have been fabricated bottom-up. However, the bottom-up approach offers the unique opportunity to fabricate very small nanostructures down to the one-digit nanometer range beyond the limits of current lithography techniques. Another advantage of self-organized fabrication of semiconductor nanostructures is the inherent parallel approach, in which billions of nanostructures are generated in parallel.

The focus of this article is the self-organized growth of semiconductor structures with lateral dimensions below 100 nm. Semiconductor quantum-well structures are nanostructures in the growth directions and not lateral nanostructures, and will not be considered in this article. The actual growth techniques used to fabricate the nanostructures like molecular beam epitaxy (MBE) and chemical vapor deposition (CVD) will be considered in separate articles. The methods used to analyze the nanostructures are scanning tunneling microscopy (STM), scanning force microscopy (AFM or SFM), transmission electron microscopy (TEM), and low energy electron microscopy (LEEM). Different properties of semiconductor nanostructures, and the applications of self-organized nanostructures in devices are discussed elsewhere in this encyclopedia. As examples for the self-organized growth of nanostructures, material systems such as Si/Ge and GaAs/InAs are used predominantly.

After introducing the self-organized semiconductor nanoislands grown on planar substrates, the aligned growth on prestructured samples is discussed. Subsequently, self-organized nanowires grown on facetted surfaces and the growth of monolayer thick wires by step-flow growth are presented. Finally, the growth of nanowires by vapor liquid solid (VLS) epitaxy and hybrid systems, where nanowires aligned to lithographically defined structures are fabricated, are presented.

Physical Principles of Self-Organized Growth

Semiconductor nanostructures can be fabricated by self-organization using heteroepitaxial growth, which is the growth of a material B on a substrate of a different material A. In heteroepitaxial growth, the lattice constants of the two materials are often different. The lattice mismatch for the two most commonly used material systems Si/Ge and GaAs/InAs is 4.2% and 7%, respectively (schematically shown in Figure 1a). This lattice mismatch leads to a buildup of elastic stress in the initial two-dimensional (2D) growth in heteroepitaxy. In the case of Ge heteroepitaxy on Si, the Ge is confined to the smaller lattice constant of the Si substrate, that is, the Ge is strained to the Si lattice constant. This results in a buildup of elastic stress (Figure 1b). One way to relax this stress is the formation of 3D Ge islands. In the 3D islands, only the bottom of the islands is confined to the substrate lattice constant. In the upper part of the 3D island, the lattice constant can relax to the Ge bulk lattice constant and reduce the stress energy this way (Figure 1c). This growth mode characterized by the formation of a 2D wetting layer and the subsequent growth of (partially relaxed) 3D islands is called Stranski–Krastanov growth mode.

The driving force for the formation of self-organized semiconductor nanoislands in heteroepitaxial growth is the buildup of elastic strain energy in the stressed 2D layer. As a reaction to this, a partial stress relaxation by the formation of 3D islands can lower the free energy of the system. The process of island formation close to equilibrium is a trade-off between elastic relaxation by formation of 3D islands which lowers the energy of the system and an increase of the surface area which increases the energy. Apart

Figure 1 (a) Schematic representation of Si and Ge crystals with different lattice constants, (b) buildup of elastic strain energy during 2D growth with Ge confined to the Si lattice constant, and (c) elastic relaxation by formation of 3D islands (Stranski–Krastanov growth). In the upper part of the 3D island, the lattice constant relaxes towards the Ge bulk constant. The usual form of the 3D islands is a pyramid and not like the one shown in this schematic sketch.

from the formation of 3D islands, there is another process which can partially relax the stress of a strained 2D layer: the introduction of misfit dislocations. This corresponds to the removal of one lattice plane of a compressively strained 2D layer. If a lattice plane is removed in regular distances in the 2D layer, a misfit dislocation network forms.

Depending on the growth parameters, temperature, and growth rate, the self-organized growth can be close to equilibrium or in the kinetically limited regime. Close to equilibrium, that is, at high-growth temperatures or low-deposition rates, the occurring morphology (strained layer or 3D islands or a film with dislocations) is only determined by the energies of the particular configurations. The morphology with the lowest energy will be formed. If the growth is kinetically limited, the activation barriers are important. For instance, an initially flat strained layer can transform to a morphology with 3D islands or to a film with dislocations. What actually happens depends on the kinetics of the growth process, that is, on the activation energy for formation of 3D islands compared to the activation energy for the introduction of misfit dislocations.

Semiconductor Nanoislands

Stranski–Krastanov growth occurs in InAs/GaAs growth. An example of InAs nanoislands grown on a GaAs substrate is shown in the atomic force microscopy image in Figure 2. The InAs islands were grown by MBE at a growth temperature of 800 K. The width of the islands is 20 nm and the height 6 nm with a density of 10^{10} cm^{-2} . The challenges in the growth of these semiconductor islands are to grow islands of the desired size and density and with a high-size uniformity. In general, a higher growth temperature generally leads to the formation of larger islands; a higher growth rate leads to the formation of smaller islands. The size of the islands increases with the coverage. Often the density of the islands saturates at an early stage of the growth. These are general trends which may depend on the material system and the particular deposition technique. In some cases (self-limiting growth), the size of the islands saturates and the density increases with coverage. This kind of growth mode leads to a high-size uniformity of the islands. The size uniformity achieved in self-organized growth of semiconductor islands can be as small as $\sim 10\%$. For optoelectronic applications, the nanoislands have to be capped (i.e., embedded in a semiconductor to prevent oxidation of the islands under ambient conditions where the optic measurements are performed) and care has to be taken that they change their shape and composition

Figure 2 InAs nanoislands grown on a GaAs surface imaged by AFM. (Courtesy of A Lorke; reproduced with permission from Warburton RJ (2002) *Contemporary Physics* 44: 351; © Taylor & Francis Ltd. (<http://www.tandf.co.uk>).)

during the capping process. The confinement of charge carriers in all three directions gives rise to atomic-like energy levels. Quantum dot lasers operating at room temperature have now been realized. The islands grown on a flat substrate are usually not ordered laterally due to the random nature of the nucleation process. In the following sections, it is shown how nucleation at specific sites can be achieved.

Lateral Positioning of Nanoislands by Growth on Templates

On homogenous substrates, the location of the nanostructured islands formed were not predictable due to the stochastic nature of the nucleation process. It is desirable to position islands at specific (preselected) locations. This is desirable if the islands are used as functional units of nanoelectronic devices. Electric contacts can be structured easier when the location of an island is predefined. The approaches are now discussed where island nucleation occurs not randomly, but at specific locations. These predefined locations are usually specific sites on regularly prestructured substrates. Examples of such prestructured substrates are: regularly stepped substrates, faceted substrates, a regular arrangement of dislocations, or long-range surface reconstructions.

An example of ordered nucleation at a prestructured substrate is shown in Figure 3. Here Ge islands nucleate above dislocation lines. An SiGe film is grown on an Si(001) substrate. At the interface between the SiGe film and the substrate, dislocations form. The driving force for the formation of the dislocations is the relief of elastic strain, which arises due to the different lattice constants between the Si substrate and a Ge/Si film on this substrate. Due to the crystal structure of the substrate, the dislocations are aligned in straight lines along the two perpendicular high-symmetry directions of the substrate. During annealing, the dislocations form a relatively regular network, due to a repulsive elastic interaction between the dislocations. Figure 3 shows growth of Ge islands on this prestructured substrate. Rows of islands grow preferentially above the dislocation lines. The nucleation of Ge islands is more favorable at the relaxed areas above the dislocations, which have a lattice constant closer to that of Ge than the strained areas of the SiGe film, where the lattice constant is confined to that of the Si substrate. Islands have a lower energy if they grow with their natural lattice constant compared to growth at a different lattice constant (strained islands). This leads to a preferred nucleation of Ge islands above the dislocations. The nucleation does not occur randomly at the surface, but simultaneously at sites which have the same structure. This can lead to a narrower size distribution than for the growth on unstructured Si(001) substrates.

In the case of the growth on a prestructured substrate, another process of self-organization occurs (before the growth of islands) during the formation of the regular arrangement of the defect structures. Here, it is often a repulsive elastic interaction, which leads to a regular distance between steps or dislocations under equilibrium conditions. Since island nucleation occurs at the defect sites, the distances are determined by the distances of the defects. Nucleation at predefined defect sites has two advantages over the random nucleation. First, the islands are located at specific sites and second, the size distribution is narrower due to simultaneous nucleation at sites with identical environment.

Vertical Stacking of Nanoislands

A nucleation of nanoislands preferentially above existing ones can be achieved when a new layer of Ge (InAs) islands is grown on top of an Si (GaAs) spacer layer. If the spacer layer is sufficiently thin, the nucleation of islands occurs just above pre-existing islands. This vertical stacking of islands is shown in Figure 4 and can be explained as follows: the lattice constant of the top part of the Ge islands is increased close to the bulk constant. Subsequent Si deposition leads to an increased lattice constant of the Si spacer layer just above the Ge islands. Upon the nucleation of the next Ge island layer, Ge islands nucleate preferentially at locations on the Si spacer layer where the lattice constant is closest to the Ge lattice constant. This is just the case above the Ge islands. The residual strain field of the Ge islands in the lower layer seeds the nucleation in the upper layer. It was observed that the size uniformity of the 3D islands in subsequent layers is improved.

Semiconductor Nanowires

Nanowires on Facetted Surfaces

Some surfaces such as the Si(1 1 3) surface are known to facet, that is, to form alternating regions with a very high step density (step bunches) alternating with flat surface regions. Subsequent growth of Ge can result in preferential growth of nanowires in the step-bunch region. This effect is even more pronounced in Si/Ge multilayers. In Figure 5, a cross-sectional TEM image of a stack of five alternating depositions of Ge and Si is shown. Ge nanowires with a thickness of ~ 4.5 nm and a width of ~ 100 nm are formed. The formation of these nanowires is explained as a strain relaxation effect of Ge growing at the step-bunch regions where it can relax the elastic strain more effectively than on a compact 2D layer. After growth of an Si buffer layer, the next SiGe wire structure nucleates above the previous one. This is a strain-induced effect similar to the one shown for the vertical stacking of the islands.

Monolayer Thick Wires at Step Edges

Regular surface steps can be used to fabricate monolayer thick Ge wires using step-flow growth. Pre-existing step edges on the Si(1 1 1) surface are used as templates for the growth of 2D Ge wires at the step edges. When the diffusion of the deposited atoms is sufficient to reach the step edges, these deposited atoms are incorporated exclusively at the step edges and the growth proceeds by a homogenous advancement of the steps (step-flow growth mode). If small amounts of Ge are deposited, the steps advance only some nanometers, and narrow Ge wires can be grown. A key issue for the controlled fabrication of nanostructures consisting of different materials is a method of characterization, which can distinguish between the different materials on the nanoscale. In case of the important system Si/Ge, it has been difficult to differentiate between Si and Ge due to their similar electronic structure. However, if the surface is terminated with a monolayer of Bi, it is possible to distinguish between Si and Ge. Figure 6a shows an STM image after repeated alternating deposition of 0.15 atomic layers of Ge and Si, respectively. Due to the step-flow growth, Ge and Si wires are formed at the advancing step edge. Both elements can be easily distinguished by the apparent heights in the STM images. It turns out that the height measured by the STM is higher on areas consisting of Ge (red stripes) than on areas consisting of Si (orange stripes). The assignment of Ge and Si wires is evident from the order of the deposited materials (Ge, Si Ge, Si and Ge, respectively in this case). The initial step position is located right from the grown Ge wires. The step edge has advanced towards the left after the growth of the nanowires. The reason for the height difference in STM between Si and Ge is the different electronic structure of a Ge–Bi bond compared to an Si–Bi bond. The apparent height of Ge areas is ~ 0.1 nm higher than the apparent height of Si wires (Figure 6b). The width of the Si and Ge wires is ~ 3.5 nm as measured from the cross section (Figure 6b). The nanowires are 2D with a height of only one atomic layer (0.3 nm). Therefore, the cross section of a 3.3 nm wide Ge nanowire contains only 21 atoms (Figure 6c). The height difference arises due to an atomic layer of Bi which was deposited initially. The Bi floats always on top of the growing layer because it is less strongly bound to the substrate than Si or Ge. The Si/Ge wires are homogenous in width over larger distances and have a length of several thousand nanometers. Different widths of the wires can be easily achieved by different amounts of Ge and Si deposited.

Free-Standing Semiconductor Nanowires Grown by Vapor Liquid Solid Growth

In the VLS method, small catalytic nanoparticles (often gold) induce the growth of a homogenous rod of a semiconductor, with the diameter of the rod determined by the nanoparticle. The gold nanoparticles can be fabricated by heating a thin evaporated gold film, which breaks up and reshapes into nanoscale droplets. Alternatively, gold aerosol nanoparticles with sizes of a few tens of nanometers are used. The gold nanoparticles form a eutectic alloy with the substrate material (for instance, GaAs). Using MBE or metallorganic vapor phase epitaxy, nanowires can be grown. These nanowires are different from the ones discussed so far, in that they are free-standing on the substrate and grow vertically. The previously considered nanowires were epitaxially grown along their length on the substrate or even embedded into the substrate during growth.

The VLS method was used for the Si/Ge and the GaAs material system. This growth method can even be used to grow semiconductor heterostructures within the nanowires with atomically sharp interfaces. Figure 7 shows an InAs nanowire (green) with several InP barriers (red). The rapid alternation of the composition is controlled by the supply of precursor atoms to the eutectic melt supplied as molecular beams. Of particular interest is the fact, that the very small cross section allows efficient lateral relaxation of the nanowire, thereby providing freedom to combine materials with very different lattice constants to create heterostructures within the nanowire. The problem of incorporation of misfit dislocations, when a critical thickness is exceeded, does not occur due to the small lateral size of the nanowires. The VLS method is also used to grow semiconductor heterostructures, not along the wire, but radial heterostructures, the so-called core-shell structures.

Figure 7 Composition profile of an InAs nanowire, containing several InP heterostructures, using reciprocal space analysis of lattice spacings with a TEM. InAs lattice spacings have been color-coded with green and InP spacings with red. Figure 8 (a) Schematic of the core-shell growth of a radial Ge/Si structure (b) TEM image of a Ge/Si core-shell nanowire. Scale bar is 50 nm. (c) Elemental mapping along the cross section showing the Ge (red circles) and Si (blue circles) concentrations. (Reproduced with permission from Lauhon LJ, Gudiksen MS, Wang D, and Lieber CM (2002) Epitaxial core-shell and core-multishell nanowire heterostructures. *Nature* 420: 57.)

The synthesis of Si/Ge core-shell nanowires by chemical vapor deposition is achieved by the following process schematically shown in Figure 8a. Initially a Ge nanowire is grown by vapor phase epitaxy growth from a gold nanoparticle. In this case, the substrate serves only as a support and the nanowires are not epitaxially connected to the substrate. The deposition temperature is chosen so low that no germane (GeH_4) is decomposed along the wire and radial growth is suppressed. Only axial growth occurs by the VLS mechanism at the gold nanoparticle. Subsequently, a boron-doped Si shell is grown by CVD. The addition of diborane serves to lower the decomposition temperature of silane (SiH_4) and “turns on” the radial growth. Figure 8b shows a TEM image of the Ge core (imaged darker) and the Si shell (lighter gray) with a diameter of ~ 50 nm. The elemental TEM cross-sectional mapping shown in Figure 8c shows the radial chemical composition in a wire (core diameter 26 nm, shell thickness 15 nm). By oxidation of a shell of the radial heterostructure, it is possible to build a coaxially gated nanowire transistor.

Hybrid Systems – Combination of Lithography and Self-Organized Growth

In hybrid methods, self-organization is combined with lithographic patterning. In this approach, self-organization is used to form nanostructures on a smaller scale than the one accessible by lithography. Most importantly, the hybrid methods provide a direct contact of nanostructures formed by self-organization to lithographically patterned structures. As an example, the self-organized growth of Ge islands in oxide holes is shown in Figures 9a–9d. The starting surface is a silicon substrate with a thin oxide layer at the surface. Electron lithography is used to remove the oxide and form holes of a diameter of $0.5\ \mu\text{m}$ where the bare Si surface is

Figure 9 (a–d) Growth of Ge islands in holes on an oxidized Si substrate. (Reproduced with permission from Kim ES, Usami N, and Shiraki Y (1999) *Semiconductor Science and Technology* 14: 257; © IOP Publishing Limited.)

exposed. Self-organized growth of Ge leads to the formation of Ge islands, which can be smaller than the size scale of the electron beam lithography. The gas phase growth of Ge is selective, that is, Ge only grows inside the holes in the oxide and not on the oxide itself. Figure 9 shows the nucleation of Ge islands in the holes in the oxide for different growth temperatures. At lower temperatures, the island density is so large that several islands nucleate in one oxide hole. If the temperature is increased finally, only one Ge island nucleates in each oxide hole. The size of the Ge island is smaller than the lithographically defined oxide hole. This approach is called lithographic downscaling. However, the positioning of the islands is not perfect. As seen in Figure 9d, the position of the Ge island inside the oxide hole is not defined but is rather randomly in the center or at the corner of the oxide hole. Due to the fact that the Ge does not grow on the oxide, the edges of the oxide hole are not sinks for deposited Ge atoms. Therefore, the Ge adatom concentration is homogenous across the hole, and the nucleation of the Ge island is random within the oxide hole. If the edges of the hole were sinks for Ge atoms (for instance, if the edges of the hole consisted of Si), the adatom density would have a maximum at the center of the hole and the nucleation of the Ge islands would occur preferentially at the center of the oxide holes.

A simple structure formed by lithographic methods is a mesa (from the Spanish table), which is a flat terrace separated from the rest of the wafer by trenches. A silicon mesa structure is imaged by electron microscopy and shown in Figure 10. It has been observed that the growth of Ge on this mesa leads to preferential nucleation of Ge islands at the mesa edges. Figure 10 shows a regular alignment of Ge islands along the mesa edges. This preferred nucleation of islands at the convex part of the surface profile is quite

Figure 10 Regular alignment of Ge islands at the edge of a mesa which was fabricated by optical lithography. (Reproduced from Vescan L (1989) *Journal of Crystal Growth* 194: 173, with permission from Elsevier.)

Figure 11 Cross-sectional TEM image of vertically stacked GaAs nanowires and AlGaAs barriers aligned along a lithographically defined V-groove. unexpected. Considering the surface curvature alone, the chemical potential is lowest at locations with a concave curvature. Atoms diffuse toward the lower chemical potential, that is, to the concave parts of the surface. This reasoning is true for homoepitaxy. In heteroepitaxy, another contribution is important: the strain-dependent contribution to the chemical potential. The convex regions are most favorable for strain relaxation of the strained Ge wetting layer covering the Si substrate. Therefore, the strain contribution to the chemical potential has a minimum at convex edges. In the current case, this strain-induced contribution to the chemical potential overwhelms the curvature contribution and leads to a minimum in the total chemical potential at the convex edges. Therefore, these convex edges with a minimum in the chemical potential provide a favorable nucleation site for Ge islands.

Also, nanowires can be fabricated, aligned to lithographically defined structures. V-grooves can be defined by lithography and anisotropic wet chemical etching with a low-etch speed for the crystal plane forming the side facets of the V-groove. The formation of nanowires at the bottom of the V-groove is induced by the self-limiting nature of the growth front of AlGaAs on the grooved substrate. Vertically stacked arrays of GaAs/AlGaAs nanowires exhibiting 5–10% size uniformity have been demonstrated (Figure 11). The layer structure consists of GaAs nanowires separated by $\text{Al}_{0.42}\text{Ga}_{0.58}\text{As}$ barriers. The formation of the crescent-shaped GaAs wires is based on the formation of slow-growing side facets along the V-grooves. The migration of adatoms away from these side-walls toward the V-groove bottom produces the concave surface profiles in the corners of the V-grooves.

Abstract

Epitaxy refers to the growth of well-oriented crystalline layer on top of the other. The ability to produce such layers with high crystalline quality allows to form novel material combinations that do not exist in nature. The emerging property of artificial is important not only for fundamental studies but also for the application. Therefore various growth techniques have been developed, which are widely applied in different branches of solid state electronics. Here, we describe some aspects of epitaxial growth that appear to be important from the practical standpoint and should make the reader acquainted with epitaxy.

Introduction

In 1928, Louis Royer coined the term epitaxy to describe the crystal-oriented growth of one crystalline material on top of the other (Royer, 1928). The term is composed of two Greek words *epi* ($\epsilon\pi\iota$), meaning “above”, and *taxies* ($\tau\alpha\chi\iota\varsigma$), meaning “order”. By that time the phenomenon of oriented crystal growth has been known to occur in nature, and many examples have been already documented (Barker, 1906). Pashley et al. refer to the work of Moritz L. Frankenheim in 1836 as the first recorded example of epitaxial growth of sodium nitrate NaNO_3 on a cleaved calcite crystal CaCO_3 (Frankenheim, 1836; Pashley, 1956). An earlier work by Wakkernagel in 1825 is mentioned to be disputed (Wakkernagel, 1825; Pashley, 1956).

Since then the epitaxial growth has evolved tremendously and became a key enabler in the development of modern technologies and synthesis of advanced materials. Epitaxial methods allow to achieve the structural quality that can even be superior to that obtained in the bulk. The ability of epitaxial methods to produce thin layers and multilayers of different materials, sharp interfaces, and spatially resolved doping allowed to obtain entirely novel physical properties. Light-emitting diodes, semiconductor lasers, high frequency transistors, and amplifiers are just few examples of how the development of epitaxial methods affected our daily life. Fundamental discoveries (such as quantum Hall effect, and Giant Magnetoresistance) were also brought by the development of high-quality structures.

In the epitaxy, we address two main questions—how the material grows and how to grow the materials. An epilayer (a layer of material formed by epitaxial growth) on a substrate forms from a metastable phase brought by deposition of amorphous compound (SPE), liquid phase (LPE), vapor and gas (vapor-phase epitaxy). The driving force for the formation of an epilayer is the chemical potential difference between metastable and stable phases of material. The crystalline phase of the epilayer material will try to minimize the total energy of the system. Therefore, the surface tensions are important for the epitaxial growth. When two materials grown on top each other are isochemical in their composition, we refer to the homoepitaxial growth process. In an ideal homoepitaxial growth the epitaxial layer is the continuation of a bulk crystal so that any evidence of substrate–film interface is absent. In such a growth, the homoepitaxial layer can have a higher crystal structure quality (e.g., less defects) or the material can be chemically doped, producing a thin conducting layer. When two materials combined together in an epitaxial way are heterochemical, we refer to heteroepitaxial growth and the synthesized structures are called heterostructures.

Fig. 1 Vapor-phase epitaxy is widespread growth method. Other epitaxial techniques include liquid-phase epitaxy (LPE) and solid-phase epitaxy (SPE).

Vapor-phase epitaxy is perhaps the mostly employed and widespread epitaxial method. Depending on the transport mechanism of gaseous species, we distinguish chemical vapor deposition (CVD) and physical vapor deposition (PVD) (Fig. 1). CVD is subclassified according to the chemistry of source gases (MOCVD = metal-organic CVD), growth conditions, etc. PVD refers to the vaporization of source materials in vacuum. The classes of PVD methods are again distinguished by the vaporization methods (thermal evaporation, sputtering). Famous PVD methods are pulsed laser deposition (PLD), where the vapor is produced by laser ablation, and molecular beam epitaxy (MBE), where the source material is vaporized by thermal heating. Metalorganic MBE (MOMBE) is a hybrid method of CVD, and PVD allows to overcome the limitation of MBE and produces high-quality semiconductor and recently even oxide structures.

This article touches some aspects of epitaxy that are important from the practical point of view and should help the reader to get acquainted with this topic. An interested reader is referred to the “Further reading” section.

Substrate and lattice matching

The growth process of epitaxial layers (also epilayers or epitaxial film) is influenced by the substrate at the very initial stage. The formation of the first epitaxial layer is pivotal for the growth of the next following layers, as its quality will dictate the subsequent growth process. Therefore, the selection of the appropriate substrate is crucial for achieving high crystalline perfection of the epitaxial layers. The substrates may require some pretreatment to obtain a clean crystalline surface with atomically flat terraces before initiating the growth. The preparation steps can include mechanical polishing, chemical treatment, degassing/oxidation, and annealing. The preparation procedure depends on the substrate material and its crystal orientation, whereas specific recipes may already be established. The choices for substrates and especially of those with good crystallinity are limited. Therefore, epitaxial growth happens between materials with not only different chemical compositions but also different structural parameters. The condition on similar crystal structure for epilayer and substrate is not strict. It should be noted that the epitaxial layers and the substrate can have different crystallographic orientation and even different crystal structures. From a pure geometrical consideration there can be such crystal orientation relationships between substrate and epilayer for which the three-dimensional film and substrate lattices coincide most closely at their two-dimensional interface (Balluffi et al., 1982; Zur and McGill, 1984). However, if the size of the common superlattice, formed by lattice coincidence, is large, the chemistry at the interface may play a major role and the epitaxial relation between the substrate and the deposit may not be obvious.

There are several ways how the difference in structural parameters (lattice mismatch) can be accommodated at the interface. If the interaction across the interface is weak, such as in van der Waals systems (graphene and other 2D layered materials), the epilayer will not be strained and will lie on the substrate. The weak forces at the interface can maintain the rotational alignment with the substrate. A more common situation occurs when the epilayer is chemically bonded to the substrate. The growth process depends strongly whether the epilayer is coherent or incoherent with the substrate. The growth is incoherent, when the epilayer assumes any in-plane lattice constant to minimize the free energy. In case of coherent growth, the epilayer adopts the in-plane lattice constant of the substrate as shown in Fig. 2A. The resulting elastic strain energy increases the free energy significantly. To quantify the degree of lattice mismatch, a parameter is defined:

$$f = \frac{a_{\text{film}} - a_{\text{sub}}}{a_{\text{sub}}} \quad (1)$$

where a_{sub} is the lattice constant of the substrate and a_{film} is the lattice constant of unstrained epilayer. Epitaxial layers with larger lattice constants than the substrate are under compressive strain, while the converse results in tensile strain. Since the strain imposed by the substrate is of a 2D character, the epilayer's lattice parameter perpendicular to the interface will change in such a way that its internal energy is minimized. The change of the lattice constant is by the three-dimensional form of Hooke's law. The resulting strain components are parallel and perpendicular to the surface. They are opposite in sign since the natural tendency of the strained structure is to preserve the volume of the unit cell. It is important to emphasize that such a crystallographic approach to match the substrate and the epilayer may not always be sufficient. One of the strongest points of epitaxy is that it can also stabilize crystal phases, which are not stable in the bulk form (Bruinsma and Zangwill, 1986). Thermodynamical consideration of the growth

Fig. 2 Crystal lattice accommodation: (A) Substrate strains the epilayer by imposing the in-plane lattice constant of the epilayer. Out-of-plane lattice constant alters so that the volume of the unit cell is preserved. (B) Elastic strain of the epilayer relaxes by forming defects, when a critical layer thickness is exceeded.

dictates that the epitaxial stabilization is governed by the interplay between surface diffusion and the nucleation energy during the growth. Therefore, elemental tin assumes metastable diamond structure on the (001) surface of InSb and CdTe (Farrow et al., 1981), and anatase phase of TiO_2 is stabilized on SrTiO_3 (001) (Hsieh et al., 2002). Similarly such approach is demonstrated for the growth of several other oxides such as SrMnO_3 , BaMnO_3 , and CaCuO_2 (Farrow, 1983; Gorbenko et al., 2002).

In the coherent growth, it is considered that only the epilayer is strained since it is much thinner than the substrate. However, when the substrate thickness and the epilayer thickness become comparable, the stress is distributed between both of them. Such situation is realized when a free standing membrane (so-called compliant substrate) is employed in the epitaxial growth (Lo, 1991; Teng and Lo, 1993; Jesser et al., 1999; Feng and Liu, 1983). When the elastic energy reaches a certain value, it becomes more favorable for the structure to relieve the stress by breaking and reforming the bonds, such as shown in Fig. 2. These features are called misfit dislocations. The overall strain will be reduced but the dislocation energy increases. The thickness at which the misfit dislocation forms is called critical thickness (der Merve, 1962; Matthews and Blakeslee, 1974; People and Bean, 1986). Such dislocations are local inhomogeneities, which change the heterostructure properties (by acting as a trap, scattering center, etc.) and deteriorate the device performance based on this material. Besides misfit dislocations, other types of defects can form, such as point defects, dislocations, stacking faults, twins, and antiphase boundaries in alloys and compound multilayers. All of them act degrading on the physical properties of the materials. It is the aim of epitaxial growth to avoid the defect formation as much as possible by optimizing the growth parameters, the growth conditions, and improving epitaxial technique.

Modes of film growth

Epitaxial growth takes place on a surface of a material, called substrate. Chemical elements of the desired material are supplied toward the surface in a way that depends on a particular epitaxial method. Fig. 3A exemplifies evaporation of atoms of two different species reaching the substrate surface with a step-terrace structure. Upon arrival a series of surface processes are involved in the epitaxial growth, which are schematically illustrated in Fig. 3A. Among them, the following are the most important:

- immediate re-evaporation or adsorption of species impinging on the substrate surface,
- surface diffusion and in case of molecules also dissociation,
- incorporation of the constituent atoms into the crystal lattice of the substrate or the formed epilayer
- desorption of the species not incorporated into the crystal lattice.

In all thermal processes a characteristic activation energy (for adsorption, re-evaporation, etc.) has to be overcome, whose value depends on the details of the process. Respectively, the number of particle participating in the particular process is given by the Arrhenius exponential law.

On a phenomenological level, there are three distinct modes of film growth depicted in Fig. 3B–D. One of them is Frank–van der Merwe growth mode or also known as layer-by-layer growth mode (Frank and Van der Merve, 1949). It is realized when the interaction between the atoms of deposit and the substrate is stronger than the bonding between deposited atoms. Thus the first atoms condense on the substrate surface and form a complete monolayer. It is followed by the formation of a somewhat less tightly bound second layer. Given that the interaction with the substrate decreases with the number of epitaxial layers, the binding tends toward the value for a bulk crystal of the deposit. As a result, each new layer can start to form only when the last layer has been complete. Another growth mode occurs when the atoms of the deposit are stronger bound to each other than to the substrate. In such case the epitaxial material favors the formation of islands. Therefore, this growth mode is called island growth mode or Volmer–Weber growth mode (Volmer and Weber, 1926).

Fig. 3 Thin film growth. (A) Schematic representation of film growth mechanism on the surface. Two species are supplied to the growth surface. Several processes are possible: adsorption (attaching to the surface), desorption (re-evaporation from the surface), diffusion, nucleation/incorporation. (B) Frank-Van der Merwe growth mode. (C) Volmer-Weber growth mode. (D) Stranski-Krastanov growth mode. (E) Balance of surface tension forces acting on the epitaxial layer defines the growth mode.

An intermediate growth mode is layer-plus-island growth mode also known as Stranski–Krastanov growth mode (Stranski and Krastanov, 1938). After the formation of one of few monolayers, the subsequent layer growth becomes unfavorable and islands start forming on top of the full layers. Many factors might account for this mixed growth mode. Among them are a large lattice mismatch between substrate and epitaxial film, and the symmetry or orientation of the overlayers with respect to substrate.

The occurrence of different growth modes can also be comprised in terms of the relations between surface and interface free energies γ , which describes a characteristic free energy needed to create an additional surface area (Grabow and Gilmer, 1988). Since γ can also be treated as a force per unit length of boundary, the force equilibrium between the contact point of the 3D film island and the substrate can be written as

$$\gamma_S = \gamma_{S-F} + \gamma_F \cos \phi \quad (2)$$

where γ_S is the surface free energy of the substrate surface, γ_F is the surface free energy of the film surface, and γ_{S-F} is the free energy of the substrate–film interface. Fig. 3E presents schematically the forces acting on the surface of the film formation. Respectively, the layer-by-layer growth is realized for $\phi = 0$, and the condition above becomes $\gamma_S \leq \gamma_{S-F} + \gamma_F \cos \phi$. The other limiting case is the island growth with $\phi > 0$ and thus $\gamma_S < \gamma_{S-F} + \gamma_F \cos \phi$.

This model captures also the mixed Stranski–Krastanov growth mode. At the initial stage of the growth layer-by-layer growth mode is realized. But the formation of intermediate layers alters gamma values, changing subsequently the force balance at the interface. The changes in gamma values can be understood by considering a lattice mismatch between deposited film and substrate. The lattice of the epitaxial layer tries to adjust to the substrate crystal lattice at the cost of elastic deformation energy. The transition from layer to island growth occurs when the spatial extent of the elastic strain field exceeds the range of the adhesion forces within the deposited material.

The simple relation does not consider the gas phase of material above the surface of deposited film. When the particle transfers from the vapor phase into condensed phase at some pressure p , the free enthalpy changes by:

$$\Delta G = n\Delta\mu = nkT \ln(p/p_0) \quad (3)$$

where p_0 is the equilibrium vapor pressure, n is the particle number, and $\Delta\mu$ is the change of chemical potential between solid and vapor phases. The ratio p/p_0 is associated with the degree of supersaturation. Taking the vapor phase into account, the conditions for layer-by-layer or island growth have to be supplemented. They become:

- $\gamma_S \leq \gamma_{S-F} + \gamma_F \cos \phi + CnkT \ln(p/p_0)$, layer growth
- $\gamma_S < \gamma_{S-F} + \gamma_F \cos \phi + CnkT \ln(p/p_0)$, island growth

The equations indicate that the supersaturation can be the driving force for the formation of epitaxial layers. More importantly, they indicate that the growth mode is not constant material parameter, but can be changed by varying the supersaturation condition. Layer-by-layer growth mode is favored with increasing supersaturation condition. This property is employed in the epitaxial growth of III–V compounds with MBE, where the group V component has relatively high equilibrium vapor pressure.

In case when homoepitaxial growth is realized, the balance of free energies of interface, film, and substrate surfaces predicts an epitaxial growth in layer-by-layer mode (Frank–van der Merve). However, the kinetic energy of atoms on the surface of the substrate can add variation in the thin film growth process. For a simplified consideration, interlayer and intralayer diffusion processes are of prime interest. The first process describes the atoms diffusion on a terrace, while the second diffusion process considers the atom motion across the step edge onto a lower terrace (Fig. 3A). Note that an atom traveling on a lower terrace will be incorporated at the step edge due to its higher binding energy. Depending on the relative interlayer and interlayer diffusion rates, three different nucleation process are realized:

- Step-flow mode. It takes place when the intralayer mobility is so high that all atoms reach the steps before the nucleation on the terrace occurs.
- Layer-by-layer growth. It is realized when the interlayer diffusion dominates. The diffusion length is smaller than the terrace width. The nucleation proceeds on the terraces and subsequent growth of adatom islands. This growth mode leads to a periodic change of surface morphology: the surface flatness recovers after completing the formation of an atomic layer.
- Multilayer growth. In ideal case it is realized when no atom transport takes place. Every atom stays on the level where it was deposited.

Based on this consideration, it appears reasonable that the growth mode can be tuned by adjusting the substrate temperature at a fixed deposition rate. At lowering the temperature, the step-flow growth mode goes over to layer-by-layer growth mode and reaches finally the multilayer 3D growth mode. Experimentally an ideal layer-by-layer growth is difficult to realize since the nucleation on a layer always takes place before the layer formation is fully completed. Consequently, the epitaxial surface always becomes rough after the deposition of many layers. In practice, one strives to obtain epitaxial layers with a low surface roughness. The surface atoms in the uppermost epitaxial layer differ from those in the bulk due to the absence of chemical bonding on one side. As a result, the surface atoms shift from their positions in the bulk so that a new equilibrium state is achieved. One distinguishes two main rearrangement effects. Relaxation is attributed to the shift of atoms normal to the surface. In this case the lateral periodicity is preserved with respect to the bulk. Usually few top most layers are involved in this rearrangement type. Reconstruction is another

type of atom rearrangement on the surface. Here the surface energy is minimized when the atoms restore some broken bonds. This is accompanied by the shift of atoms parallel to the surface. Thus the unit cell of the reconstructed surface differs from that in the bulk. The observation of diffraction pattern, such as performed with RHEED (see section below), can detect the surface reconstruction.

Material characterization

The quality of the synthesized film can be accessed by various characterization techniques. The main goal of characterization is to help a grower to optimize the growth conditions for improving the crystal structure quality, reducing defects, achieving desirable stoichiometry, etc. Quality of crystal affects the physical properties of the synthesized material. The list of the characterization techniques presented here is by far not complete:

Atomic force microscopy (AFM). The technique allows to measure the roughness of the surface down to the atomic level. Scanning probe technique monitors the force between the sharp scanning tip and the sample surface. The change of the force is used to produce the images of surface. The method has also high lateral spatial resolution and can operate at ambient conditions.

X-ray diffraction and reflection (XRD). Diffraction of X-ray on the sample surface provides information on the crystal structure of epitaxial layers: lattice parameters (in-plane and out-of-plane), orientation relation between epitaxial layer and substrate, thickness the surface roughness (involving some modeling) can be measured.

Scanning electron microscopy (SEM). It is an electron microscope that provides images by scanning focused electron beam across the surface and detecting the signal from secondary or backscattered electrons. It images the surface topology, grain size and shape, film voids, microcracks, etc.

Energy dispersive X-ray (EDX). The signal of backscattered electrons in SEM is used to evaluate the chemical composition of the material. The signal comes from the thickness of about $1\mu\text{m}$ with lateral resolution of a comparable size. EDX's detection limit is 0.1% and it can detect elements with atomic number higher than 11. Usually EDX unit is installed together with SEM.

Secondary ion mass spectroscopy (SIMS). This technique allows to evaluate the composition, of the epilayer. It uses a focused ion beam to sputter the surface of the sample and analyze the ejected secondary ions. The technique allows to obtain the depth profile information on material composition. Own to its high sensitivity, SIMS is used to quantify the incorporated impurities.

Transmission Electron Microscope (TEM). It provides high-resolution plan-view lattice images and transverse film section. It can thus visualize lattice orientations, interface quality and defects, atom mixing at interface, superlattices, etc.

X-Ray photoelectron spectroscopy (XPS). It is a photoemission spectroscopy analyzing the energy of the electrons emitted from the surface as a result of irradiation by single-energy X-ray photons. XPS is a surface-sensitive method and provides information on surface composition as well as its chemical state. It detects all elements with the exception of hydrogen and helium.

Ellipsometry. The technique is based on the analysis of polarized light reflected from the sample. It probes the complex refractive index and allows to extract the information about layer thickness and roughness.

Almost all of these techniques characterize the material after the growth. An outstanding technique that can probe the surface of the substrate and monitor the growth processes is Reflection High-Energy Electron Diffraction. Since this technique is compatible with the vacuum environment, it is widely employed to monitor the growth process in PLD and MBE (Hasegawa, 2012; Ichimiya and Cohen, 2004; Haeni et al., 2000).

Reflection high-energy electron diffraction (RHEED). As the name implies, the technique exploits diffraction of electrons by surface atoms and thus probes the periodic arrangement of atoms at the surface. In this technique an electron gun (e-gun) generates a monochromatic electron beam with a typical energy of 10–50 keV, which strikes the surface of the sample at a grazing angle of about 1 degree. At this energy the electron wavelength is in sub-angstrom range, which is thus smaller than the thickness of an atomic layer. Furthermore, due to a small incident angle, the penetration depth is only few atomic layers below the surface, which explains the sensitivity of RHEED technique to the surface morphology. The diffracted electrons interfere constructively at specific angles given by the electron wavelength, crystal structure, crystal orientation, and atom arrangement on the surface. The resulting diffraction pattern can instantly be visualized on a photoluminescent screen. It is the subject of analysis since it carries the information on surface processes.

When the sample surface is smooth, the diffracted intensity is a maximum. However, when the epitaxial surface is partially covered, the diffracted intensity decreases due to destructive interference in the diffracted electron beam from different areas of the surface. Hence, when the layer-by-layer epitaxial growth mode is realized, the diffracted intensity reveals an oscillatory behavior. This is visualized by plotting the specular spot intensity as a function of time during the epitaxial growth. The oscillations are routinely employed to measure the thickness of the epitaxial films and superlattice layers since each period of oscillations corresponds to the completion of one monolayer. Furthermore, by counting the number of RHEED oscillations, one can calibrate the deposition flux, control alloy composition, and adjust it respectively. If the surface does not become smooth after completion of each monolayer, the amplitude of RHEED oscillations decays gradually due to destructive interference. The RHEED oscillations are characterized by their period, amplitude, phase, damping of the oscillations, their initial behavior at the beginning of growth, and their recovery after growth. These features can provide valuable information about the growth process.

Besides the diffraction spots from the surface, which are anticipated from the kinematic scattering analysis, additional intensity lines and curves appear in the diffraction pattern. They are the result of the dynamical scattering and are known as Kikuchi lines.

They emerge as a result of nonlinear effects and originate from electrons scattered incoherently from the crystal by phonons, plasmons, defects, or electron–electron interactions. The observation of sharp and clear Kikuchi lines is an indication of a flat and crystalline surface (Hasegawa, 2012).

Epitaxy techniques

Various deposition techniques can be distinct by the kinetic energy of particles impinging on the substrate surface and can be grouped in three kinetic energy regimes (Cuomo et al., 1991). Low energy process (on the order of 0.1 eV) encompasses chemical vapors deposition and thermal evaporation. Here the particle kinetic energy is on the order of the thermal energy associated with the temperature of the substrate. Atoms impinging on the substrate surface thermalize almost immediately with the substrate, get adsorbed, and diffuse on the surface until they get permanently bonded at a nucleation site. At a given temperature, the condensation rate can be increased by increasing the vapor flux. At elevated substrate temperature the enhanced kinetic energy of atoms facilitates to overcome the surface traps and to find energetically more favorable states. This results in a growth of films with fewer defects. In this kinetic energy regime, the material forms thermodynamically stable state.

Another deposition regime with energies above 1 eV is realized when the material flux is created by sputtering, laser vaporization, etc. The energy of such species corresponds to the equivalent temperatures exceeding the temperature of the accommodating surface. It is rather associated with the atomic energy and bond strength. In this case the interaction with the surface becomes significant. As a result the impinging species can create defects on the surface, which can become important for the formation of interfaces between materials. In this energy regime metastable material phases can form.

In the other deposition regime, the kinetic energies are above 100 eV and the particles can even penetrate the surface and be implanted in the material.

Chemical vapor deposition

CVD is a widely used material deposition technique in which thin films are synthesized on a heated substrate via a chemical reaction of supplied precursors. In contrast to PVD, such as MBE and PLD (discussed later), CVD heavily relies on chemical reactions. Therefore, thermodynamics governs the CVD reaction and indicates the direction in which the reaction proceeds. Perhaps the first report on using the CVD technique dates back to 1946, when Teal et al. deposited silicon film on ceramic surfaces by flowing silicon tetrachloride (SiCl_4) and hydrogen gas (Teal et al., 1946). Due to the chemical reaction

a smooth silicon film forms at 1100°C. CVD process consists of several steps which are pictorially depicted in Fig. 4:

- Transport of reactants to the deposition region
- Diffusion of reactants from the main gas stream to the wafer surface. Prior to that, the reactant gases can undergo reaction and form an intermediate reactant.
- Adsorption on the wafer surface and diffusion on the surface
- Surface processes (chemical decomposition and reaction, site incorporation, nucleation) lead to the thin film synthesis and growth. Additional stimulators (light, plasma, temperature) can be introduced to promote the chemical reaction.
- Desorption of byproducts from the surface and their transport away from the deposition region

Fig. 4 Chemical vapor deposition. Schematic representation of processes during CVD. Shown are the sequence of gas transport and reaction contributing to the thin film growth. The molecules are dissociated from the growth surface and undergo a chemical reaction on it. The by products are removed from the active zone.

The main components of a CVD system are the reaction chamber and gas handling system (gas delivery and exhaust gas treatment system). In a most common configuration the reactor is a horizontal quartz tube, where the substrate is placed on a boat/susceptor made of quartz or graphite. A gas inlet injector is connected to one side of the tube, where the gas supply is regulated by the mass flow controller. In case the precursor is in a solid state form, it can be supplied to the deposition region either by sublimation or by dissolution in an appropriate solvent. The other side of the reactor is connected to the exhaust to remove the by products of thin film growth. Potentially hazardous by products should be removed by introducing suitable traps. The reactor can be connected to the vacuum system to purge the deposition chamber before the deposition and to achieve the necessary pressure for the transport of reactants. The temperature of the substrate can be raised locally by resistance heating or by raising the temperature of the entire reaction chamber using an external furnace. For obtaining high quality film it is essential not only to select the proper substrate (for instance due to its catalytic ability or other chemical properties), but requires also the optimization of the growth condition such as temperature, gas flow rate, pressure etc.

There are various CVD types which differ from each other by reactor (growth chamber) configuration, operation conditions, substrate heating methods, stimulators to promote the chemical reaction, precursor type, etc. Among them are:

- Metal-organic CVD (MOCVD), also known as MOVPE (metal-organic vapor-phase epitaxy), employs metal-organic precursors to form thin films. The precursors are usually volatile and toxic so that a particular precaution has to be taken. This CVD method is widely used for the growth of III-V semiconductor structures for optoelectronic applications.
- Plasma-enhanced CVD uses plasma (partially ionized gas) to promote the chemical reactions.
- Atomic layer deposition (ALD). The precursors are introduced in a pulsed manner. They are absorbed in a self-limiting chemical reaction on the substrate surface. Between pulses the carrier gas removes the remaining precursors. Layer-by-layer growth can be achieved, whereas the film thickness can be controlled by the number of precursor cycles.

Started with the growth of silicon-based coating, CVD became an important technique for semiconductor industry to produce thin films. It also plays an important role in developing and exploring novel materials. Versatile CVD techniques are employed for the large-scale synthesis of graphene and polymeric thin films, and 2D layered materials such as transition metal dichalcogenides (Sun et al., 2021).

Liquid-phase epitaxy

LPE is the crystal growth deposition technique of a single crystalline layer from a liquid phase (a solution or melt) on a substrate acting as a seed (Dawson, 1972; Stringfellow, 1982). The idea behind the growth technique is to create a supersaturated solution of a material that has to be deposited. The substrate is then brought in contact with the melt, from which a solid-state layer precipitates as an epitaxial film on the substrate. The growth process occurs close to thermodynamic equilibrium so that the system reaches a thermodynamic state of lower free energy. This distinguishes LPE from deposition techniques such as PLD, MBE, and vapor-phase epitaxy (VPE). Although multiple layer systems can be synthesized from solutions of different compositions, the feasibility to combine them is driven by the thermodynamic processes. Therefore, materials must have, for instance, similar or controllable liquidus temperatures. The growth can also be impeded by the lattice mismatch between seeding and epitaxial layers. Furthermore, the mass transport and diffusion between the layers limit the interface sharpness and can result in unintentional compositional and doping gradings. Because of thermodynamics, LPE is sensitive to temperature changes, solution composition, surface tension, quality of seeding substrate, etc.

The great advantages of LPE growth are the high growth rate, exceptional high purity crystals with low defect density (impurities tend to segregate rather than to be incorporated into the epilayer), and high selectivity on patterns, substrates, and faceted growth, which can produce shaped crystals and selectively nucleated crystals with high aspect ratios. This made LPE to the pioneering growth method to produce the optoelectronic devices (LED, laser, solar cells) based on II-VI and III-V semiconductors (Nelson, 1963; Rupprecht et al., 1967; Woodall, 1972; Alferov et al., 1969). Other compounds, including oxides and superconductors, can also be grown with LPE (Ehrentauf et al., 2006; Klemenz and Scheel, 1993; Nagarajan et al., 2011; Yamada et al., 1993). See "Further reading" for more information on this epitaxy method.

Solid-phase epitaxy

SPE refers to the type of growth when a material undergoes a transition from amorphous phase to a crystalline phase. Usually the material is deposited in an amorphous form on a crystalline substrate, which serves as a template for crystal growth (Mayer et al., 1968; Cho, 1969a; Marks et al., 2021). When heated, atoms in the amorphous phase reorder by local bond rearrangements at the crystalline-amorphous interface. The material phase transformation can also be induced by laser, electron, or ion irradiation. An annealing step to recrystallize layers during the ion implantation or to heal defects can also be considered as a SPE (Streit et al., 1984; Norga et al., 2006). SPE is also employed for growing a buffer layer to improve heteroepitaxy of lattice-mismatched heterostructures. See "Further reading" for more information on this epitaxy method.

Molecular beam epitaxy

MBE is a physical vapor deposition technique, which is frequently used in research laboratories and industry. The technique was introduced in 1960s by A. Y. Cho and J. R. Arthur (Arthur, 1968; Cho and Arthur, 1975; Cho, 1969a, 1970). MBE is low-energy deposition technique in ultra-high vacuum. The constituent elements of the crystalline solid are supplied from the source to the substrate as a directed ray of neutral molecules and atoms, so called molecular beam. Such transport implies that the mean free path of species is larger than the distance between the source and the substrate. As a result, the atoms experience no collision before they reach the substrate. A thin epitaxial layer crystallizes via reactions between molecular beams, and a substrate surface holds at high temperature. Therefore, the composition of the epilayer depends on the relative arrival rates of the constituent elements. By controlling the evaporation rate of the source, the arrival rate of molecular beam and thus the epilayer composition can be adjusted. Such a control of epilayer stoichiometry is one of the key strengths of MBE growth. A low growth rate ($1\mu\text{m h}^{-1}$) assures that the species absorbed on the substrate surface can diffuse (Fig. 3A). Therefore, MBE allows to achieve smooth epilayer surface. Each molecular beam source is equipped with a mechanical shutter, which is placed in front of it and is used to start and stop the growth fluxes by blocking the emitting flux from the substrate in a time much shorter than the time needed to grow a monolayer. This allows to establish a sharp interface between two materials. A high purity of original element source and high vacuum help to reduce the contamination of epilayer by impurities. The vacuum environment offers an excellent opportunity to monitor the growth process in situ. RHEED is frequently installed in the growth chambers. Thus MBE can produce high-quality thin film structures with layer thickness precision on the atomic level.

Fig. 5 is a schematic view of an MBE chamber that contains essential elements of MBE equipment independent of its purpose. Not shown is a load-lock chamber system that allows to introduce the wafer (or substrates) into the growth chamber without breaking the high vacuum.

Pumping system

It is one of the essential components to assure the molecular beam propagation between source and substrate. The mean free path L changes with the pressure P as $L = 5 \times 10^{-3}/P$, where the distance is given in cm and the pressure in Torr. Thus under high vacuum of 10^{-9} Torr, the mean free path is about 5×10^6 cm. The vacuum is generated by pumps and cryoshrouds. The layout of the pumping system is crucial for an MBE setup; it must also assure an effective evacuation of residual source gases and reactant byproduct gases. Depending on the purpose, an MBE system can be equipped with various pump systems, such as turbo-molecular pump, ion pump, and cryogenic pump.

Material evaporation source is another important components of an MBE layout. Depending on the material to be evaporated, different sources for producing molecular beam are available.

Fig. 5 MBE Schematic view of the growth chamber of an MBE machine. The drawing is the courtesy of VEECO.

Material evaporation source

Cells. Knudsen' cell is by far the most important type of evaporation source in a molecular beam system. It is filled with ultrahigh purity materials, which reduces incorporation of impurities in the epilayers. Basically a Knudsen cell is a tubular crucible (made of pyrolytic boron nitride, quartz, tungsten, or graphite), filled with the desired chemical element and is heated resistively up to the level of desired material flux. The Knudsen cells installed in MBE have large opening and thus they are different from the true Knudsen source (Knudsen, 1915), which should have an orifice size comparable with the mean free path of the gas molecule at the temperature of evaporation. The material flux from the cell and its angular distribution in a real MBE system depend not only on the crucible shape but also on the evaporant fill level. Owing to the large thermal mass the cell temperature and thus the evaporation rate cannot be changed quickly. The temperature is usually controlled with a thermocouple. A special type of effusion cell is a cracker cell. Some elements (such as As and P) evaporate as tetramers, although their dimers show a better sticking coefficient to the substrate surface and thus a better growth performance. Breaking of tetramers (As_4) in dimers (As_2) is accomplished in a cracker cell, which is a Knudsen cell having two zones of temperature. The low temperature zone produces the tetramer vapor and the high temperature zone cracks the tetramers to dimers. The cracking efficiency depends on the catalyst, whereas Ta and Rh are very effective.

Gaseous sources. Alternative material flux source was initially introduced by Panish due to difficulty of growth of semiconductor compounds with elemental source of phosphorus (Panish, 1980; Panish et al., 1985). AsH_3 and PH_3 gas sources were introduced to grow InGaAsP. The hydrates are injected into the chamber and are dissociated in cracker cell so that dimers of elements are formed. Also metalorganic (MO) compounds are employed as alternative material sources, which thus borrows an idea from chemical vapor deposition technique (MOVPE). Metalorganic compounds are less thermally stable and can dissociate directly on a growing substrate. The by products are removed from the environment, whereas the cryopumps can be employed to maintain a good vacuum condition. MBE system equipped with MO source is often called MOMBE. The advantage of it is that MO needs a low temperature to produce sufficient flux; it is stored outside of MBE chamber and thus can be readily replaced; a high growth rate can be achieved. MO compounds are however toxic and less pure than the elemental source material.

E-gun. The operation of Knudsen cells is limited to a temperature of about 1400C. Yet, some elements require a higher temperature to be evaporated and to obtain a sufficient material flux for the epitaxial growth. In this case, the materials such as Ti, Si, Mo, and W. can be evaporated using intense beams of high-energy electrons, so called e-beam gun (Kasper, 1982; Koenig et al., 1979; Ota, 1983). The heating energy is transferred by electrons on just an evaporating surface of target. Although such evaporation technique is more prone to flux instability, the introduction of active feedback loops between evaporation parameters and flux can minimize the fluctuations. Since this technique can evaporate a large number of elements, the e-beam evaporators are frequently employed in the epitaxy (Yamamoto et al., 2013).

Laser was also employed for heating the sources in MBE growth of II-VI compounds. With this technique, $\text{Hg}_{1-x}\text{Cd}_x\text{Te}$ epitaxial layers and superlattices were grown (Cheung and Madden, 1987; Cheung et al., 1986).

Flux measurement and stoichiometry

Accurate flux measurements and flux stability are crucial for the growth of high-quality films with well-defined stoichiometry. Fluxes from the effusion cells can be characterized by various techniques. Quartz crystal microbalance (QCM) measures the flux by relating the shift in the resonance frequency to the accumulation of mass on the probe located at the substrate position. Beam equivalent pressure (BEP) can be obtained by inserting an ion gauge in front of the substrate, so called beam flux monitor (BFM). Atomic absorption spectroscopy and cross-beam mass spectroscopy are other examples for monitoring the material flux of each effusion cell. Despite the variety of methods, an excellent control of flux and thus stoichiometry is difficult. Moreover, the flux stability will also depend on the stability of the cell temperature. All these lead to the deviation of the desired compound composition. The desired structure accumulates defects or can even form other crystalline phases. As a result, the physical properties of the desired compound are altered. Yet, the thermodynamics can enable a stoichiometric compound composition within some range of growth parameters (substrate temperature and material flux). Such thermodynamic regime is also known as an adsorption-controlled growth. One talks also about an opening of a growth window. A prerequisite for this is that one of the constituent elements has to be volatile. This requirement is fulfilled for the growth of III-V semiconductors, which has thus significantly contributed to the success of semiconductors' growth. The respective thermodynamic conditions can be estimated from the equilibrium lines in a pressure-temperature diagram (Arthur, 1968; Cho, 1971). The lower bound is given by As condensation on a Ga-rich GaAs surface, while the upper bound is given by the vapor pressure curve of As. Between two boundaries, sufficient As is supplied to saturate each Ga monolayer, and any excess As desorbs from the surface and enters the vapor phase. Thus, the growth rate is determined by the Ga flux and the self-regulated growth can be obtained. Since the equilibrium lines are separated from each other by orders of magnitude in the As gas pressure, the request on the precise control of the flux and temperature is relaxed. In principal, if the growth conditions are within the growth window, an identical crystalline compound forms. If the parameters are outside of the growth window, the compound decomposes, for instance by forming liquid Ga and solid As phases. The regime of adsorption-controlled growth is also realized for some oxide compounds with volatile elements Pb and Bi, such as PbTiO_3 , BiFeO_3 , BiMnO_3 , and $(\text{Rb}, \text{Ba})\text{BiO}_3$ (Theis et al., 1998; Ihlefeld et al., 2008; Lee et al., 2010; Hellman and Hartford, 1990).

Oxide compound

The growth of oxides constitutes one of the important fields in the material science, as the oxides show a diverse range of physical phenomena in bulk and thin films and therefore are considered as a promising material platform for realizing novel functionalities (Schlom et al., 2008; Hwang et al., 2012). High-quality structures are realized in an MBE chamber equipped with a suitable oxygen source, which can be molecular oxygen O_2 (suitable for easy oxidizing compounds), oxygen plasma (activated by RF plasma source), or ozone, which is the most reactive and the cleanest oxygen source (Schlom et al., 1988; Eckstein et al., 1989; Berkley et al., 1988, 1989). By using a highly reactive oxidizer a long mean free path should be guaranteed to avoid gas-phase reactions. Usually the nozzle of oxygen line is positioned about 10 cm away from the substrate surface. A complete oxidation of epilayers is always a matter of concern in oxide MBE. Yet, it is possible to achieve high-quality oxide structures. ZnO is one of the examples. The heterostructures based on ZnO feature high electron mobility, giving rise to a variety of quantum phenomena (Tsukazaki et al., 2010; Falson et al., 2011, 2016, 2015; Maryenko et al., 2018, 2021). High-quality ternary oxides, such as $SrTiO_3$ perovskite, are grown by employing metalorganic precursor (MO) as the source for Ti element, that is titanium(IV)isopropoxide (TTIP, $Ti[OCH(CH_3)_2]_4$). A high vapor pressure of TTIP enables an adsorption controlled growth and therefore offers an excellent control over the epilayer stoichiometry (Endo et al., 1991; Jalan et al., 2009a, b, c; Brahlek et al., 2018). Once TTIP molecule reaches the hot substrate surface, it decomposes in nonvolatile TiO_2 and by products consisting of volatile C_3H_6 and H_2O . TiO_2 reacts with SrO formed on the surface, leading to the formation of a stoichiometric $SrTiO_3$ layer. The structures synthesized in this way allowed to achieve high electron mobility (Son et al., 2010) and to demonstrate the quantum Hall effect for the first time in oxide perovskite structures (Matsubara et al., 2016). Oxide MBE with MO sources is referred as hybrid MBE.

The approach to synthesize oxide perovskite with MOs has been extended on the growth on vanadium perovskite, using vanadium-triisopropoxide (VTIP) as a source of vanadium (Moyer et al., 2013; Brahlek et al., 2018) and high mobility $BaSnO_3$, employing hexamethylditin (HMDT) as a precursors to supply tin (Chambers et al., 2016). The reactive environment of oxide growth requires the use of oxidation-resistive materials for components that are particularly exposed to high temperatures. Heating of substrate is also an important part of consideration for oxide MBE. The usage of laser heating system instead of resistive heaters allows not only to achieve even higher growth temperatures but also to reduce the heat load on the growth environment. As a result, the incorporation of undesired impurities collected on the chamber walls of the heating system is reduced. Due to the local heating by laser, the heat capacitance is reduced and the quick change of the growth temperature can be achieved, which can be favorable for growth protocols requiring the temperature changes. High temperature can even prepare in situ the substrate surfaces suitable for the growth (Jaeger et al., 2018; Braun et al., 2020).

Fig. 6 is the photograph of an oxide MBE machine installed at RIKEN. It is equipped with several retractable Knudsen cells, supply of metal-organic precursors, and ozone source. Laser heater system allows to achieve temperature well above 1000C. The pumping system, consisting of turbomolecular pump and cryopump, allows to remove the by products of metalorganic

Fig. 6 Photograph of oxide MBE VEECO GEN10 installed at RIKEN. Additionally it is equipped with the ozone source and gas cell for supply of metalorganic precursor. The laser beam for substrate heating is guided by the optical fiber to the growth chamber.

precursors effectively. Cryogenic panels cooled with liquid nitrogen minimize the thermal load of the growth chamber and allow to trap impurities from the gas phase during thin film deposition.

Pulsed laser deposition

PLD is one of the PVD process techniques, where the material to be deposited is ablated (evaporated) by highly energetic laser beam focused on the starting material, so called target. This growth technique emerged due to the development of laser technology. In fact, the first demonstration of PLD growth technique was in 1965 by Smith and Turner, who used ruby laser to synthesis optical coatings (Smith and Turner, 1965). However, a broad proliferation of PLD growth method has been triggered by the work by Dijkkamp and coworkers demonstrating the thin film growth of high temperature superconductors $\text{YBa}_2\text{Cu}_3\text{O}_7$ (Dijkkamp et al., 1987). Since then PLD has been employed for synthesis of all kinds of materials, encompassing oxides, nitrides, carbides, organic materials, polymers, and metallic systems. Because of the similarity with MBE growth technique, one finds for PLD growth also the notation as laser-assisted MBE or laser MBE.

Fig. 7 shows the main concept of PLD process. A pulsed laser beam passes through an optical window of a vacuum chamber and is focused onto a target, where it is partially absorbed. A dense layer of vapor forms in front of the target, whose temperature and pressure increase during the light absorption process, resulting in a partial ionization of the ablated materials. The formed layer expands from the target surface and appears as a forward-directed luminous plume. During the expansion, internal thermal and ionization energies are converted into the kinetic energy of ablated particles. The ablation plume provides thus the material flux for the film growth. The threshold power of high energy laser needed to produce such a plume depends on the target material, its morphology, and the laser pulse wavelength and duration. A typical laser fluence amounts to $1\text{--}10\text{ Jcm}^{-2}$. Excimer laser or high harmonics of Nd:YAG solid-state laser can provide such high energy laser pulses and are frequently employed in PLD setups. For an efficient ablation, the optical absorption coefficient of the target material should be high at the laser operation wavelength. The target materials do not have to have the same phase as the desired thin film; only the cation stoichiometry needs to be preserved, assuming stoichiometric transfer between target and film. Each ablation pulse provides material amount sufficient for the deposition of a submonolayer of the desired thin film phase. Therefore, PLD deposition is very suitable for multilayer and interface formation where submonolayer control is required (Fig. 8).

The kinetic energy of species arriving at the substrate can modify the thin-film growth. Upon ablation the species in the ablated plume interact with the gas atmosphere introduced during the growth. So the particles, kinetic energy at the substrate surface depends on the gas parameter, mass, and pressure. Thus the kinetic energy can range from high initial energy (several hundred electron volts) with no gas atmosphere to low energies (few tenths of electron volts) from thermalization at sufficiently large ambient pressure. Upon arrival at the substrate surface, the diffusion time of the atoms usually exceeds the optical pulse duration, leading effectively to instantaneous deposition. During the time between subsequent optical pulses, the adatoms can rearrange on the surface by diffusion and are subsequently incorporated through nucleation and growth. Such a separation of the growth process in two steps, instantaneous deposition and nucleation, is unique for thin film synthesis with PLD. The two steps can be controlled independently from each other. While the instantaneous deposition rate can be controlled by adjusting the laser energy density

Fig. 7 Schematic view of PLD. The laser beam ablates the target and creates a plume that propagates toward the substrate kept at high temperature. RHEED is used to monitor the growth process. Inset shows the RHEED pattern as observed on the fluorescent screen. Spots of RHEED pattern and Kikuchi lines indicate a good film quality.

Fig. 8 Photograph of a PLD installed at RIKEN.

(pulse energy and laser focus on the target), ambient gas condition, distance between target and substrate, and the growth rate are determined by the laser pulse repetition rate. Moreover, the growth process will depend on the substrate surface preparation quality and the substrate temperature.

Besides the UHV optical view port for introducing the laser light into the growth chamber, a usual PLD chamber contains a vacuum pumping system (turbomolecular pumps) to maintain a background pressure between 10^{-6} and 10^{-11} Torr. Substrate heater, target manipulator, and gas inlet are also essential components of PLD setup. The substrate heating system can be realized in various ways; it can be a conventional SiC heater as well as halogen lamp or an infrared laser. For the deposition of oxides, halogen lamp and infrared laser are widely used, since they do not oxidize in oxygen reactive atmosphere. The substrate is usually placed about 2–10 cm away from the target. The target manipulator can be a carousel containing several targets. The targets can be in situ exchanged, facilitating the synthesis of multilayer structures consisting of different materials. Also various gases (molecular O_2 , N_2 , Ar, etc.) can be introduced into the chamber through the gas inlet during thin film deposition to promote the reaction of the evaporated species. To increase the reaction rate, oxygen plasma, nitrogen plasma, or even ozone can be introduced through the gas inlet. The growth process is monitored with the help of RHEED.

The PLD technique is probably one of the most versatile thin film synthesis methods as it offers a number of advantages (Willmott and Huber, 2000):

- Almost any material can be grown with PLD.
- The source of material evaporation (pulsed laser) is outside of the growth chamber, offering the flexibility in geometrical arrangement and material choice.
- Nearly there is one-to-one stoichiometry transfer from target to the film, even for chemically complex systems.
- There is synthesis of materials with a chemical composition far from equilibrium. This opens the way for attaining materials with novel electronic states, which cannot be obtained under thermal conditions.
- There is tunability of the growth rate due to laser operation in a pulse regime.

Besides numerous advantages that PLD can offer, there are several fundamental and technical drawbacks as well:

- Ablation target process can also produce ejecta, which will lead to the defect formation in the synthesized films.
- Target contains impurities either introduced during sintering of the target or from the source material. As a result, impurities can be incorporated into the epitaxial layers.
- high kinetic energy species in the plume bombard the surface of substrate as well as subsequently formed epitaxial layers. This results in the formation of crystallographic defects, which can be detrimental for the formation of sharp interfaces.
- The process of plume formation leads to an inhomogeneous distribution of flux and angular distribution within the plume. As a result, the synthesized structures can be inhomogeneous.
- Stoichiometric transfer from target to the desired materials is not always granted. The stoichiometry transfer can depend on the deposition condition, such as laser fluence or temperature (Groenendijk et al., 2016; Ohnishi et al., 2008; Tomar et al., 2019). For targets with volatile elements, the target has to be enriched with the respective element. The change of a stoichiometric

composition requires a fabrication of a new target. Moreover, the ablation of the target can modify its surface, which can lead to the variation of the target stoichiometry at the position of the laser focus. In extreme case the change of the target stoichiometry can lead to the decrease of the growth rate.

Sputtering

Sputtering is the ejection of particles from the target by its bombardment with energetic particles. Sputtering process relies on production of plasma through electrical discharge and electrostatic acceleration of ions, inert gas ions like argon, towards the source material. The impinging ions transmit energy and momentum to the source material and knock out the particles from the surface of the target. Ejected particles are the source material for films grown by sputter deposition. The particles ejected in sputtering are predominantly neutral atoms in the ground state, although ions and atomic clusters can also be present in the emitted flux. Such process of creating particle flux is similar to that of PLD, except that in PLD the target is ablated by laser light. There are different kinds of sputtering processes, depending on condition (reactive sputtering, bias sputtering) or configuration (ion beam sputtering, DC sputtering, RF sputtering, magnetron sputtering). For instance, magnetron sputtering implies that a magnetic field is created in the vicinity of target holder, which bends the ionized particles on a specific area of a target. This increases the deposition rate and the deposition area. Sputtering deposition technique is cost-effective, shows a high throughput and can produce large-area films. Such characteristics make the deposition technique attractive for industrial growth applications. See “Further reading” for more information on this epitaxy method.

Conclusion

Epitaxy is a broad research field concerning with the mechanism and methods to grow well-oriented crystalline layers. Over the last century a various practical methods have been developed that allowed the synthesis of an enormously large palette of materials. GaAs-based structures are a striking example of the opportunities that open when structures are optimized and the growth technique is refined (Pfeiffer and West, 2003; Pfeiffer et al., 1989; Umansky et al., 2009; Gardner et al., 2016; Chung et al., 2018, 2021). In this context, the continuous improvement of material quality, the development of new materials and their multilayers including hybrid structures is an important direction, that will enable to open new horizon not only in fundamental science but also in applications. Epitaxial methods are therefore essential for traversing along this path.

Abstract

This chapter describes general aspects of epitaxy which denotes the growth of crystalline layers with order given by a crystalline substrate. A focus is on molecular beam epitaxy (MBE) representing a powerful method for epitaxy in particular of ultra-clean two-dimensional semiconductor heterostructures, where the precise control on the composition, size, and roughness of the deposited layers enables an engineering of the band gaps and doping profiles. Using self-assembled growth schemes, also one-dimensional nanowires and zero-dimensional quantum dots can be fabricated without the need for lithography. Discussed topics are technological aspects, basics of crystal growth, epitaxy of strained layers, strain-induced and droplet-based self-assembly, and in situ growth monitoring with focus on electron diffraction.

Introduction

Epitaxy denotes a kind of crystal growth where new crystalline layers are formed with order given by a crystalline substrate. The term epitaxy reflects this oriented overgrowth by referring the Greek language with *epi* meaning above and *taxis* meaning in an ordered manner. Epitaxy can form small crystalline clusters in contact with a substrate or epitaxial layers covering the substrate at a large lateral extent. Historically, first experimental studies on the oriented overgrowth of a crystalline material on a crystalline substrate are reported 1928 by L. Rover (Poppa, 1964).

Depending on the involved materials one distinguishes between homoepitaxy where substrate and new layer are composed of the same material and heteroepitaxy where substrate and new layer are made from different materials. Homoepitaxy is technologically important for example, for the fabrication of ultra-pure and low-defect single crystals, whereas heteroepitaxy is much more flexible and allows for example, the creation of so-called heterostructures, which are stacked crystalline layers of different materials. In particular heterostructures made from semiconductor materials with different band gaps are technologically very important and enable the fabrication of layered quantum structures like quantum wells (QWS) and superlattices by the so-called band-gap engineering (Arthur, 2002). A popular material combination is here GaAs/AlGaAs which allows a significant variation of the band gap whereas the lattice constants are almost equal. In addition to semiconductors, also metallic systems (Bauer, 1982) and even organic materials (Lee et al., 2014) can be grown epitaxially.

In an idealized picture, the substrate is a perfect single-crystal characterized by the symmetry of the unit cell and the lattice constant a_{sub} . For epitaxial growth, the new layer should have the same crystal symmetry and lattice constant a_{layer} . However, epitaxy is possible also for material combinations with slightly different lattice constants, which is described by the lattice mismatch

$$f = \frac{|a_{layer} - a_{sub}|}{a_{sub}} \quad (1)$$

A lattice mismatch larger than zero induces strain energy in the crystal which can be relaxed by formation of dislocations or by switching to an island growth mode (see Section “Nucleation and epitaxial growth modes”).

Epitaxy in technology

Epitaxy is widely used for instance in semiconductor technology for the fabrication of devices where layers of elementary or compound semiconductors with controlled thickness, band gap, and doping profile are requested. Several approaches to realize epitaxial growth are applied. One major difference between the methods is the state of matter in which the source material for the new layers is supplied. In solid-phase epitaxy (SPE), an amorphous film in contact with a crystalline substrate is recrystallized during a thermal annealing step. Liquid-phase epitaxy (LPE) is a method to grow crystal layers from a molten material (Fig. 1). Here the substrate is often a small seed crystal which defines the crystallographic order of the new layers. For crystallization, the temperature of the melt is reduced to a value below the melting point or the melting point is reduced by adding a further material. For example, liquid gallium droplets in contact with a GaAs substrate can be crystallized to GaAs by adding arsenic in the so-called droplet epitaxy (see Section “Droplet-based self-assembly”). Both techniques, SPE and LPE, are used for the fabrication of semiconductor crystals with a low defect density.

However, a fast change of the source materials for the new layers, which is essential for the fabrication of heterostructures, is difficult to realize using SPE or LPE. Here, methods are advantageous where the source material is supplied as a vapor in the gas phase. In physical vapor deposition (PVD), the source materials in solid or liquid phase are not in contact with the substrate. A vapor is generated from the source materials by thermal heating (evaporation) or by irradiation with light (pulsed-laser deposition), electrons (electron-beam PVD), or ions (sputter deposition). The vapor is transported through a vacuum to the substrate and condenses there (Fig. 1). It should be noted that PVD is often used for the coating of devices where an epitaxial growth is not required. A type of PVD that is optimized for the growth of epitaxial layers is the molecular beam epitaxy (MBE, see Section “Molecular beam epitaxy (MBE)”). Another vapor-based technique for epitaxy is the chemical vapor deposition (CVD) where the source materials are supplied as chemical precursors usually from a gas source. The precursor molecules are dissociated on the substrate and the desired material is incorporated into the growing layer (Fig. 1). This is in contrast to MBE where usually elementary source materials are supplied and directly incorporated.

In a rough comparison, MBE requires expensive ultra-high vacuum (UHV) equipment, typically works at a rather slow growth speed of about 1 $\mu\text{m/h}$, and the growth is directed perpendicular to the evaporation sources. CVD uses reaction chambers with less expensive vacuum requirements, the growth speed is typically higher at about 10 $\mu\text{m/h}$, and the growth can be undirected. The usage of precursor molecules in a CVD process allows a chemically selective growth that can be used for instance for an area selective deposition (ASD) or for deposition of highly conformal thin films by sequential reaction of mono-layered precursor molecules in atomic layer deposition or epitaxy (ALD, ALE). To summarize, MBE is a rather slow and expensive technique, but allows the fabrication of ultra-pure heterostructures with excellent crystal quality and is often used for projects in fundamental research on quantum systems or as a pioneering technology to evaluate new materials or device concepts. CVD systems are usually cheaper with a higher throughput which suggests this method also for industrial device fabrication.

Molecular beam epitaxy (MBE)

The foundations of molecular beam epitaxy were established in the late 1960s by J.R. Arthur and A. Y. Cho starting with focus on III/V compound semiconductors (Cho and Arthur, 1975). MBE takes place in an UHV environment in the 10^{-10} to 10^{-12} Torr range to minimize the level of unintentional background doping. This requires a thorough preparation of the vacuum chamber, powerful vacuum pumps, and large usually liquid–nitrogen cooled cryo-shrouds inside the chamber. In solid-source MBE, pure elements are evaporated in thermally heated effusion cells, the vapor travels through the vacuum as a directed beam, and finally condenses on the substrate surface. Kinetic gas theory estimates at a pressure of 1×10^{-6} Torr inside a vapor beam a rate of gas impingement on the substrate of about 1 monolayer (ML) per s, which corresponds for GaAs to a growth speed of 1 $\mu\text{m/h}$, typical for MBE. On the other side, assuming a very low background pressure of 10^{-12} Torr inside the vacuum chamber, the rate of unintentional gas impingement is about 10^{-6} ML/s. In a worst case scenario where all impinging species are incorporated, this would result in a contaminated

Fig. 1 Illustrations of various methods used for epitaxial growth on a crystalline substrate. In liquid-phase epitaxy (LPE) a molten material in contact with a substrate is crystallized. Vapor-phase-based methods take place in a vacuum and the source material is supplied in an elementary form in physical vapor deposition (PVD) or as a precursor gas in chemical vapor deposition (CVD).

crystal. Fortunately, at usual MBE growth temperatures, only a minor part of the species contributing to the background pressure is incorporated into the growing film. Critical species during MBE of III/V-compound semiconductors are often oxygen or carbon which can significantly degrade the optoelectronic properties of the deposited layers. This indicates the total pressure as an inadequate quantity for the characterization of an MBE system. More meaningful are the partial pressures of the relevant species.

A further important point is the stoichiometry of the materials during epitaxy of compound semiconductors. As an example, for MBE of GaAs, the group III element Ga is typically evaporated at a temperature of about $T_{Ga} \simeq 900^\circ\text{C}$ and the group V element As at about $T_{As} \simeq 200^\circ\text{C}$. The different evaporation temperatures are given by the respective vapor pressures of the elements. This yields three regimes for the substrate temperature T_{sub} . For a substrate temperature $T_{sub} < T_{As}$ below the minimum temperature required for evaporation, all deposited material will stick on the substrate and the stoichiometry of the deposit must be maintained by adjusting perfectly equal fluxes of Ga and As. Due to technical limitations, equal fluxes are hard to realize and this regime usually results in the formation of nonstoichiometric films with a poor crystalline quality. The regime with $T_{sub} > T_{Ga}$ is also not applicable since here all deposited material will be re-evaporated. In the intermediate regime, $T_{As} < T_{sub} < T_{Ga}$, Ga will stick and As should be re-evaporated. However, due to a strong chemical bond between Ga and As, only excessive As without bond to a Ga atom re-evaporates. That means, for an As flux higher than that of Ga, this mechanism can provide perfectly stoichiometric GaAs layers. This example illustrates that epitaxy of stoichiometric compounds is possible, but requires appropriate temperatures and material combinations.

Assuming a sufficient group V element flux to maintain stoichiometry, the thickness and composition of a deposited layer are precisely controlled by the sum of the fluxes of the group III elements. The individual material fluxes toward the substrate are adjusted by the temperatures of the respective effusion cells. However, for abrupt interfaces between layers composed of different materials, a temperature change is not fast enough. This issue is solved by so-called shutters in front of each effusion cell, which allow an abrupt switching of the respective flux within typically 0.1 s. Considering a usual growth speed of 1 ML/s, the shutters enable the deposition of layers with thickness below one ML. For instance, closing and re-opening of an Al shutter can generate a GaAs QW embedded in AlGaAs with atomically sharp interfaces. Other important MBE grown structures are for instance quantum cascade lasers utilizing multiple QWs for intersubband transitions, or high-electron-mobility transistors (HEMTs), which is a special type of a field-effect transistor where the conductive channel is spatially separated from the doped region to reduce the charge-carrier scattering.

In the last years, the range of materials grown by MBE was expanded from the initial arsenides to other III/V compounds such as phosphides and nitrides, II/VI compounds, elementary semiconductors, oxides, diluted magnetic semiconductors, topological insulators, and organic semiconductors. Due to the high crystal quality of MBE grown material, the possibility to deposit layers of controlled band gap and doping with atomic precision, and its flexibility regarding the materials, MBE has contributed to several Nobel Prizes in Physics, including the fractional quantum Hall effect (1998), semiconductor heterostructures (2000), and solid state lighting (2014). Recent overviews on MBE are given for instance in [Orton and Foxon \(2015\)](#) and [Asahi and Horikoshi \(2019\)](#).

Nucleation and epitaxial growth modes

This section describes the basic mechanisms of epitaxial growth using an MBE configuration as example. Usually, MBE growth takes place far away from equilibrium since new material arriving on the growing surfaces covers already deposited material before this moves to surface positions with a minimal energy. That means energetically unfavorable configurations are possible and kinetic models are required for a description of the growth process.

[Fig. 2](#) gives an overview about the basic processes during MBE. Growth is driven by adatoms from the vapor beam which arrive with a rate F on a crystalline substrate. The following description assumes a single-compound material, and an atomically flat substrate surface with discrete adsorption sites given by the crystal lattice. The surface coverage θ of the new material is characterized in the units of monolayers (MLs), where a coverage of one ML indicates that in average every surface site is occupied by one adatom.

Fig. 2 Schematic illustration of the basic processes during MBE growth from a vapor beam which can be described by the rate for arrival from the beam flux F , the desorption rate R_D , and the surface diffusion rate D . The inset shows the potential landscape with the energy barrier for surface diffusion E_S , and the nearest-neighbor binding energy E_N .

After arrival, the adatoms can be incorporated into the growing film or they can be re-evaporated by desorption with a rate R_D . The probability for incorporation is described by the sticking coefficient $\alpha = (F - R_D)/F$. At usual process temperatures T , the sticking coefficient $\alpha \simeq 1$ and the adatoms migrate on the substrate surface which is called surface diffusion. Further possible processes like the exchange of new adatoms with atoms from the substrate crystal are neglected in the following: Kinetic approaches describe surface diffusion by jumps of adatoms to neighboring surface sites with a thermally activated rate $D = v \exp[-E_S/(k_B T)]$, where v is a vibrational frequency, E_S is the activation energy for surface diffusion, and k_B is Boltzmann's constant. In this picture, a single adatom on the surface will not be incorporated but instead performs a permanent diffusion. A second adatom arrives after a time interval $1/F$ and now a nucleus can be formed by a collision between the migrating adatoms. The additional lateral binding energy E_N between the neighboring adatoms inside the nucleus strongly reduces the surface diffusion rate where now for the activation energy a value $E_S + nE_N$ must be considered, with the number n of neighboring atoms. For large values of E_N , the lateral bonds inside a nucleus cannot be broken which is called irreversible aggregation. Often reversible aggregation is observed, where small values of E_N allow an escape of adatoms from a nucleus. This can result in the dissolution of a nucleus and reduce the density N of nuclei on the surface. Usually the size of a nuclei increases with deposition time and is balanced by the rates of adatom attachment and escape. With larger size, the initial nuclei are often called growth islands or clusters.

Models of nucleation and island growth often use coupled rate equations to describe the time-dependent average densities of adatoms and islands (Venables et al., 1984; Zinke-Allmang et al., 1992). With some approximations, the maximum island density can be estimated from

$$N \propto (F/D)^p \quad (2)$$

where the scaling parameter is $p \simeq 1/3.5$ for 3D islands and $p \simeq 1/3$ for 2D islands. That means, the island density increases with increasing flux F and decreases with increasing temperature and, thus, increasing diffusion rate D . In a simple picture assuming one adatom and one island on the surface, a high D means a long diffusion length and a high probability that the adatom attaches to the island before a second adatom arrives for a nucleation. On the other side, at a low D or high F , the second adatom will arrive before the first atom can attach to the existing island and the probability for nucleation of a new island is high.

As an example for the influence of the substrate temperature on the nucleation, Fig. 3 shows the density of Al and Ga droplets on an AlGaAs substrate. Such droplets are relevant for the so-called droplet epitaxy of semiconductor nanostructures (see Section "Droplet-based self-assembly"). Clearly visible is the tunability of the droplet density over several orders of magnitude. Furthermore, the slope of the droplet density versus T depends on the materials, which indicates material-dependent values of E_S and E_N . The general trend of the experimental data agrees with Eq. (2), but for a detailed analysis, more elaborated models are required. In Fig. 3, the experimental droplet densities data are quantitatively reproduced by a model based on coupled rate equations (Heyn and Feddersen, 2021).

In the literature, three possible epitaxial growth modes are assumed (Venables et al., 1984), which are illustrated schematically in Fig. 4. In the layer or Frank-van der Merwe mode, the deposited material starts with the formation of a complete monolayer on the substrate surface. After its completion, a second monolayer is formed and so on. This growth mode is usually observed for material systems where the deposited adatoms are more strongly bound to the substrate than to each other ($E_S > E_N$). Since the layer mode provides very smooth two-dimensional (2D) surfaces or heterostructures with abrupt inner interfaces, it is technologically very important for instance for the semiconductor device fabrication. In the layer plus island or Stranski-Krastanov mode, growth starts similar to the layer mode with the formation of monolayers which form the so-called wetting layer (WL). However, after WL formation, subsequent layer growth is energetically unfavorable and the initial 2D growth front switches to the formation of

Fig. 3 Density N of Al and Ga droplets deposited by MBE on an AlGaAs substrate for droplet epitaxy as function of the deposition temperature T . The experimental data (symbols) are taken from atomic force microscopy (AFM) images. The lines are calculated using a model based on coupled rate equations with two material-dependent model parameters, the energy barrier for surface diffusion E_S and the nearest-neighbor binding energy E_N (Heyn and Feddersen, 2021).

Fig. 4 Schematic representation of the three crystal growth modes: layer or Frank-van der Merwe mode, layer plus island or Stranski-Krastanov mode, and island or Volmer-Weber mode. θ represents the coverage in monolayers (MLs).

three-dimensional (3D) islands. The layer plus island mode is often observed in strained systems with a substantial lattice mismatch between the substrate and the deposit. Applications of the Stranski-Krastanov mode are for instance the self-assembled generation of semiconductor quantum structures (see Section “Strain-induced self-assembly”). In the island or Volmer-Weber mode, the deposited material forms 3D islands directly on the substrate surface. This happens when the deposited adatoms are more strongly bound to each other than to the substrate ($E_S < E_N$). Island growth can be also utilized for the self-assembled creation of semiconductor quantum structures in the so-called droplet epitaxy (see Section “Droplet-based self-assembly”).

Strain in epitaxy

Often, material combinations used for heteroepitaxy have different lattice constants causing a lattice mismatch f (see Eq. (1)). A prominent exception is the material combination of AlGaAs and GaAs, where f is negligible small. For most other material combinations, a lattice mismatch induces strain in the growing crystal which is energetically unfavorable. When the strain energy becomes too high, it can be relaxed by formation of dislocations or by switching to layer plus island growth.

Fig. 5A illustrates as an example the different regimes for growth of $\text{In}_x\text{Ga}_{1-x}\text{As}$ on a GaAs substrate, with the indium content x . The lattice mismatch for pure InAs on GaAs is 7.3%, for $\text{In}_x\text{Ga}_{1-x}\text{As}$ it becomes $f = x \cdot 7.3\%$. Transitions between the three different regimes are observed at so-called critical thicknesses. In the pseudomorphic regime for rather thin layers, the strain energy is not relaxed and can be used constructively. For instance, pseudomorphic silicon layers on SiGe substrates are used in semiconductor industry for the fabrication of fast transistors, where the strained Si exhibits a reduced electron effective mass and, thus, a higher electron mobility. Another example is self-rolling semiconductor nanotubes (Prinz et al., 2000; Schmidt and Eberl, 2001). Fig. 5D

Fig. 5 (A) Regimes of strain-energy relaxation for growth of $\text{In}_x\text{Ga}_{1-x}\text{As}$ on GaAs. Three regimes are separated by critical thicknesses that depend on the lattice mismatch f (which is controlled by the indium content x). (B) Cross-sectional transmission electron microscopy (TEM) image of an InAs quantum well (QW) on a GaAs wafer with a virtual substrate and a metamorphic buffer for strain relaxation (Mendach et al., 2002). (C) Cross-sectional TEM image of a strain-induced InAs quantum dot (QD) grown in Stranski-Krastanov (SK) mode. (D) Scanning electron microscopy (SEM) image of a self-rolling nanotube, where the rolling mechanism is driven by the strain energy inside of a GaAs/InGaAs bilayer.

shows such a nanotube composed of a GaAs/InGaAs bilayer. Here, the outer InGaAs layer with larger lattice constant than the inner GaAs layer causes a strong bending of the bilayer which finally leads to its self-rolling.

At a larger layer thickness, the regime changes from pseudomorphic to metamorphic where the strain is relaxed by misfit dislocations. Both regimes are separated by the critical thickness above which misfit dislocations are formed. This critical thickness can be calculated according to Matthews and Blakeslee (1974) and is plotted in Fig. 5A. Growth in the metamorphic regime can be used for the fabrication of strain-free so-called virtual substrates with an adjustable lattice constant. The example in Fig. 5B shows a pure InAs QW on a GaAs wafer with a virtual substrate and a metamorphic buffer for strain relaxation Mendach et al. (2002). Coming from the bottom, the structure is started with a GaAs/AlAs superlattice (SL) for surface smoothing and cleaning. This is followed by a sequence of layers where the In content is increased from 15% up to 75% in steps of 10% every 100 nm. According to Fig. 5A, the first 100-nm thick layer with $x = 15\%$ is in the metamorphic regime and misfit dislocations are formed at the interface to the substrate. Also visible are misfit dislocations at the other interfaces toward higher x (Fig. 5B). The last 430-nm thick layer with 75% In content has a low dislocation density and represents an unstrained virtual substrate for the InAs QW.

At an In content above 40%, growth in layer plus island mode is energetically favorable in comparison to the formation of dislocations. This regime is used for the creation of QDs in Stranski–Krastanov mode (Fig. 5C) and is addressed in more detail in Section “Strain-induced self-assembly.” The critical thickness for QD formation can be measured using in situ reflection high-energy electron diffraction (RHEED), which is discussed in Section “In situ growth monitoring.”

Self-assembly of nanostructures

In the context of crystal growth, the term self-assembly means a structural reorganization of the incoming material to form an ordered structure without external direction. For vapor-based growth methods like MBE, self-assembly often yields a clustering of the planarly deposited material. Regarding the three epitaxial growth modes (see Section “Nucleation and epitaxial growth modes”), obviously the layer mode is not self-assembled since here the structure of the new layers directly follows the planar deposition. On the other side, both, layer plus island and island mode, rely on a transformation of the planarly deposited material into localized clusters which is considered as a self-assembled process. The application of both modes for the generation of self-assembled nanostructures is addressed in the following sections. A more detailed overview on self-assembled nanostructures is given for instance in Henini (2008).

Strain-induced self-assembly

The strain-induced self-assembly of InAs 3D islands on GaAs substrates during MBE in the Stranski–Krastanov mode has become very popular after the first demonstration in 1994 (Leonard et al., 1994; Madhukar et al., 1994; Moison et al., 1994). Such InAs 3D islands exhibit a zero-dimensional (0D) density of states which motivates the name quantum dots (QDs). They are highly interesting for fundamental research and for applications in the quantum information technology, where single dots act as quantum emitters at the usual wavelengths for fiber-based communication. Furthermore, the 0D density of states suggests QD ensembles for efficient lasers or solar cells. Self-assembled Ge QDs on Si represent another popular material combination for strain-induced QD formation.

The driving force for self-assembly in Stranski–Krastanov mode is the lattice mismatch f between the substrate crystal and the deposited material (see Section “Strain in epitaxy”). The strain energy of a thin layer with lattice constant a_{layer} on a thick substrate with smaller lattice constant a_{sub} can be estimated using Hooke’s law $E_{\text{strain}} = \varepsilon/(2\mu^2)V[(a_{\text{layer}} - a_{\text{sub}})/a_{\text{layer}}]^2 = \varepsilon/(2\mu^2)V[f/(f+1)]^2$ with Young’s modulus ε , the Poisson number μ , and the volume V of the deposited layer. This identifies two possible mechanisms for a reduction of E_{strain} : First, a reduction of the strained volume and second, a reduction of f . The first mechanism is the origin for the formation of 3D QDs instead of a planar layer since atoms in higher regions of the islands are almost unstrained. The second mechanism is the driving force for intermixing of the QDs with material from the substrate.

Fig. 6 illustrates the evolution of a typical growth process in Stranski–Krastanov mode. First a strained planar layer is formed, the so-called WL. Due to a strong chemical attraction to the substrate, atoms in the WL will not form 3D islands for strain relaxation. With increasing deposited coverage θ , strained 2D islands are formed on top of the WL. So far, growth is similar to growth in the layer mode (see Section “Nucleation and epitaxial growth modes”). Above a critical coverage θ_C , the strain energy inside the 2D islands exceeds a threshold value and now growth switches abruptly to the formation of 3D QDs for a reduction of the strain energy. This abrupt transition from 2D islands to 3D QDs can be observed in situ using electron diffraction (see Section “In situ growth monitoring”) and for InAs on GaAs typically values of $\theta_C = 1.5 \dots 2$ ML are measured. The relevant process for the 2D to 3D transition is the upward migration of atoms from the island border toward the upper regions of the dot. A further reduction of the strain energy by intermixing with substrate material is often observed Joyce et al. (1998). This changes the composition of the QDs and with this also their optoelectronic properties. Fig. 5C shows an example of a self-assembled InAs QD grown in Stranski–Krastanov mode on GaAs. The surface density and structural properties of the dots can be tuned by the process parameters like deposition temperature, growth speed, and deposited volume.

Fig. 6 Schematics of the surface morphology evolution during strain-induced formation of self-assembled 3D QDs in Stranski–Krastanov mode with the wetting layer (WL). θ_c denotes the critical thickness for the transition from growth of strained 2D islands to formation of 3D QDs.

Droplet-based self-assembly

The utilization of metal droplets during semiconductor epitaxy was initiated in 1990 for Ga droplets on ZnSe (Chikyow and Koguchi, 1990). In the following, the method was expanded for other material systems and widely used for the self-assembled fabrication of semiconductor quantum structures like QDs or rings (Mano et al., 2000; Gurioli et al., 2019). Droplet epitaxy takes place in two steps. In a first step, the droplet material is deposited and in a second step the droplets are crystallized into semiconductor quantum structures. The droplets are formed in Volmer–Weber mode (see Section “Nucleation and epitaxial growth modes”), where the deposited adatoms are more strongly bound to each other than to the substrate ($E_S < E_N$). Usually metal droplets like Ga, In, or Al are used for droplet epitaxy, which are in a liquid state and have no crystalline structure. That means the mechanism for self-assembly is fundamentally different compared to the strain-driven Stranski–Krastanov mode.

The morphology of a liquid in contact with the surface of a solid material is determined by the surface and interface tensions. In detail, there is the surface tension γ_L of the liquid, the surface tension γ_S of the solid substrate, and the interface tension γ_{SL} . The shape of a droplet is characterized by the contact angle α_C between the liquid and solid surfaces, which can be calculated using Young’s Equation $\cos \alpha_C = (\gamma_S - \gamma_{SL})/\gamma_L$. For Ga droplets on AlGaAs, values of $\alpha_C = 45^\circ \dots 55^\circ$ are observed and for Al droplets on AlGaAs $\alpha_C = 60^\circ \dots 70^\circ$ (Heyn et al., 2015). The general mechanism for droplet formation is illustrated for Ga droplets on GaAs as an example. Here the tensions are $\gamma_L = 0.67 \text{ J/m}^2$, $\gamma_S = 1.04 \text{ J/m}^2$, and $\gamma_{SL} = 0.61 \text{ J/m}^2$ (Heyn et al., 2015). For a planar Ga layer, the total energy would be $\gamma_L + \gamma_{SL}$. Droplet formation yields a total energy according to $(1 - A)\gamma_S + 4A\gamma_L + A\gamma_{SL}$ with the normalized contact area A between droplets and substrate. Since $\gamma_S < \gamma_L + \gamma_{SL}$, this simple estimation indicates that droplet formation reduces the total energy for a small A . Furthermore, it predicts a minimal total energy for a minimal A , that is, only one droplet on the surface. Since this is experimentally not observed, it can be concluded that the system is not in equilibrium and that kinetic processes are also important. An example for a kinetic modeling of droplet densities is given in Section “Nucleation and epitaxial growth modes,” Fig. 3.

For a functionalization as semiconductor quantum structures, the liquid metal droplets can be crystallized. Using MBE, a typical process starts with the droplet deposition on a semiconductor substrate. For instance Ga droplets are deposited on AlGaAs with only the shutter of the Ga effusion cell open (see Section “Molecular beam epitaxy (MBE)”). After droplet formation, the Ga shutter is closed and the As shutter is opened for the crystallization of the Ga droplets into epitaxial GaAs quantum structures. As a huge advantage in comparison to QDs grown in Stranski–Krastanov mode, droplet epitaxy allows the generation also of unstrained structures. On the other side, the fabrication of quantum structures with high optical quality by droplet epitaxy requires thoroughly optimized process conditions.

As an alternative to droplet epitaxy, the deposited droplets can be used also to drill self-assembled nanoholes into a substrate surface (Wang et al., 2007; Heyn et al., 2015). This local droplet etching (LDE) allows the integration of self-assembled top-down strategies into the usually bottom-up MBE growth. The nanoholes are shaped similar to an inverted cone and can be filled with a material different from the substrate for functionalization. For instance, filling of nanoholes in an AlGaAs substrate with GaAs allows the fabrication of strain-free GaAs QDs.

Vapor–liquid–solid (VLS) growth of nanowires

A further droplet-based growth method is the VLS growth of semiconductor nanowires in CVD or MBE. In contrast to the droplet epitaxy (see Section “Droplet-based self-assembly”), here the droplet material is not consumed by the process but instead acts as a kind of catalyst initiating the growth of nanowires for example, for one-dimensional quantum systems (Gazibegovic et al., 2017). In a first step, the droplets (often Au) are deposited on a semiconductor surface. Here, the melting point of the droplet material can be reduced by alloying with substrate material. During the subsequent nanowire growth, the droplets adsorb atoms from the vapor beams which then crystallize at the liquid–solid interface. This provides a directed growth of the nanowires with the droplet on top. In this sense, the droplets represent a guidance for the planarly deposited source materials for a localized growth. The structural parameters of the nanowires like diameter and length can be adjusted by the process conditions. Furthermore, also core-shell nanowires can be fabricated by switching the process conditions from catalytic nanowire growth to conventional growth. Here, a semiconductor material with a large band gap surrounds a nanowire core with smaller band gap.

In situ growth monitoring

In situ growth monitoring allows the evaluation of crystalline properties during growth and, thus, is an important prerequisite for the precise control of epitaxial growth and for the optimization of the process parameters. Real-space imaging techniques like TEM or AFM are hard to realize in an environment for epitaxial growth, reciprocal space-based methods are much easier to implement. A technique often used in MBE is RHEED (Cho and Arthur, 1975). Here, an electron beam is directed to the substrate surface under a shallow incident angle of about 1 degree and the reflected electrons are detected by a phosphorous screen usually in combination with a camera for data analysis. This geometry has technical advantages since the equipment for RHEED does not conflict with the position of the evaporation sources. Furthermore, due to the shallow incidence angle, the electrons interact mainly with the topmost atoms of the growing crystal which yields a high surface sensitivity for this technique. The RHEED technique provides detailed information about the macroscopic surface morphology as well as about the local arrangement of the surface atoms (the so-called surface reconstruction). Using RHEED for an in situ monitoring allows the study also of dynamic phenomena.

Fig. 7 illustrates typical RHEED pattern for surface morphologies with a different dimensionality. Diffraction patterns can be interpreted as the intersection of the Ewald sphere with the reciprocal lattice. For a surface with 3D islands, the diffraction conditions are close to transmission diffraction through a bulk crystal and the reciprocal lattice is composed by regularly arranged lattice points. Fig. 7A shows as an example for a diffraction pattern from a rough GaAs wafer surface with 3D islands before MBE growth. GaAs crystallizes in a zinc blende lattice, which is a face-centered cubic (fcc) lattice. The reciprocal lattice of fcc is body-centered cubic (bcc), which is represented by the spots in the RHEED pattern. For a smooth 2D surface morphology, the electron beam interacts mainly with the topmost layer of the sample and the reciprocal lattice consists of so-called crystal truncation rods (CTRs). The CTRs can be broadened by surface features like 2D islands. Here, the interaction with the Ewald sphere typically yields parallel lines as diffraction pattern, the so-called streaks (Fig. 7B). For nearly atomically smooth surfaces, the CTRs are almost sharp and the interaction with the Ewald sphere yields a pattern of spots arranged on a so-called Laue circle (Fig. 7C).

A further important feature indicated by the RHEED data in Fig. 7 is the surface reconstruction (Cho and Arthur, 1975), where atoms located at a crystal surface minimize their energy by taking positions with spacing and symmetry different from the bulk lattice. The bulk lattice constant is visible in the horizontal spacing of the 3D reciprocal-lattice points in Fig. 7A. In contrast to that, for a 2D surface morphology in $[110]$ azimuth the spacing between the reciprocal-lattice elements is $1/2$ (Fig. 7B) and in $[-110]$ azimuth it is $1/4$ (Fig. 7C). This indicates a (2×4) surface reconstruction, where in $[110]$ azimuth every second real-space lattice position deviates from the bulk and in $[-110]$ azimuth every 4th position. For GaAs surfaces, the $2 \times$ periodicity is caused by the formation of As dimers on the surface and the $4 \times$ periodicity often by missing dimers. Depending on the process parameters like temperature and As pressure many different surface reconstructions are observed.

The above RHEED-features surface reconstruction and widening of the CTRs allow already an extensive evaluation of the evolution of the surface morphology during growth. For the layer growth mode, further information can be gathered from the dynamic evolution of the RHEED specular reflex (Fig. 7B). In contrast to the RHEED patterns related to diffraction, the specular reflex is originated by reflection. During growth in layer mode, the intensity of the specular reflex often shows strong oscillations (Fig. 8A), the so-called RHEED oscillations (Neave et al., 1983). RHEED oscillations are attributed to the periodic nucleation and coalescence of 2D islands (Fig. 4), where step edges at the island borders cause diffuse scattering and reduce the intensity of the specular reflex (Clarke and Vvedensky, 1987). Usually the period of one RHEED oscillation indicates the growth of one monolayer, which allows an easy and accurate calibration of the beam fluxes from the growth rate-determining effusion cells. A further analysis of the RHEED oscillations can provide insights into the dynamics of island nucleation.

Fig. 7 Schematics of the reciprocal space for different real-space surface morphologies together with examples of corresponding reflection high-energy electron diffraction (RHEED) pattern. The dashed green lines denote the direction of the incident electron beam and the orange lines illustrate the cross sections between the Ewald sphere and the respective reciprocal lattices. The RHEED pattern is taken from (001) GaAs surfaces with (A) 3D islands in $[110]$ azimuth, (B) small 2D islands in $[110]$ azimuth, and (C) large 2D islands in $[-110]$ azimuth. SR in (B) indicates the specular reflex which is used to measure RHEED oscillations.

Fig. 8 (A) RHEED oscillations during layer growth of AIAs on a (001) GaAs substrate. (B) RHEED pattern from a (001) GaAs surface in $[-110]$ azimuth showing a Laue circle. (C) RHEED pattern from a (001) GaAs surface with self-assembled InAs QDs in $[-110]$ azimuth.

Also the transition from layer growth to the formation of 3D islands in Stranski–Krastanov mode can be detected by RHEED. Fig. 7B and C show as an example a GaAs surface before and after InAs deposition for QD generation. Clearly visible is the transition in the RHEED pattern from a smooth 2D surface featuring a Laue circle to 3D transmission diffraction. The RHEED pattern from the surface with QDs shows the InAs reciprocal lattice-related spots plus so-called chevrons linked to the bulk reflexes. The chevrons represent CTRs caused by the tilted crystalline surfaces of the QDs. In particular the presence of chevrons is a clear indication for QD formation and allows an evaluation of the QD shape. Furthermore, the critical coverage θ_c for QD formation (Fig. 5) can be determined from the instant of the 2D to 3D transition.

To summarize, RHEED provides real-time information about the growth rate, the surface reconstruction and roughness, kinetic phenomena like nucleation, and the dynamics and morphology of self-assembled QDs. Additional methods for monitoring are used to obtain further information. Reflectance anisotropy spectroscopy is sensitive to the roughness of epitaxial layers, the growth rate, and the sample temperature. Pyrometry and band-edge thermometry allow a temperature monitoring of the sample. Residual gas analysis allows a characterization of the background species; it can be used for studies of surface chemistry and kinetics, and it is important for leak tests.

Conclusion

Epitaxy is a striking type of crystal growth which is a premise for the fabrication of a large number of semiconductor devices for modern electronics and for future quantum information technologies. In particular the molecular beam epitaxy (MBE) is an established technology for the epitaxial growth of ultra-clean semiconductor heterostructures, where the precise control on composition, size, and roughness of the deposited layers enables a versatile engineering of the band gaps and doping profiles. Exceeding the possibilities of 2D heterostructures, the utilization of self-assembly mechanisms for a localized growth enables also the generation of 1D nanowires and 0D QDs without the need of any lithography. This comprehensive control on band gap energies, doping, size, and dimensionality of the created semiconductor structures suggests MBE as an essential tool for devices studied in fundamental research as well as for industrial applications.

Abstract

This article gives a background on basic mechanisms of critical currents, which are determined by the physics of interacting vortices and their pinning by multiscale defect structures in superconducting materials.

Key points

- Single-vortex and collective pinning
- Strong-to-weak pinning crossover
- Optimum pinning configurations
- Pinning and current blocking by grain boundaries
- Thermally-activated flux creep

Nomenclature

B	Magnetic induction
E	Electric field
E_c	Electric field criterion for J _c
f_p	Elementary pinning force
H	Magnetic field
H*	Irreversibility field
H_{c1}	Lower critical field
H_{c2}	Upper critical field
J_c	Critical current density
J_d	Depairing current density
L_c	Longitudinal pinning correlation length
n_p	Density of pinning centers
R_c	Transverse pinning correlation length
r_p	Pinning interaction radius
T_c	Critical temperature
U(I)	Flux creep activation energy
ε	Line energy of the vortex
λ	London penetration depth
ξ	Coherence length
Φ₀	Magnetic flux quantum

Introduction

The superconducting state in the bulk of type-II superconductors exists at temperature T below the critical temperature T_c and magnetic fields below the upper critical field $H_{c2}(T)$. Such superconductors can carry weakly dissipative currents of density J smaller than the critical current density $J_c(T, H)$ in the region of the H-T-J phase diagram shown in Fig. 1. Both the critical current density $J_c(T, H)$ and the irreversibility field $H^*(T) < H_{c2}(T)$ at which $J_c(T, H^*)$ vanishes are the main parameters of merit for applications of superconductors in power transmission lines, magnets for medical magnetic resonance imaging systems, etc. (Larbalestier et al., 2001; Yao and Ma, 2021).

There are two types of superconductors, which exhibit very different mechanisms of current transport. For instance, in type-I superconductors represented mostly by pure metals, such as Al, Pb, and Sn, non-dissipative current along a wire can only flow in a narrow surface layer due to the magnetic flux expansion and the ideal diamagnetism of the superconducting state (the Meissner effect). Once the magnetic field generated by the transport current I at the surface exceeds the thermodynamic critical field H_c , a type-I superconductor switches into an intermediate resistive state at the critical current $I_c = 2\pi RH_c$ for a round wire of radius R (Tinkham, 1996). However, most superconducting alloys, intermetallic compounds, high- T_c cuprates or iron pnictides are type-II superconductors which can carry both the surface Meissner currents at low magnetic field $H < H_{c1}$ and bulk non-dissipative currents above the lower critical field H_{c1} but below the upper critical field H_{c2} . Bulk critical current densities in type-II superconductors in the mixed state at $H_{c1} < H < H_{c2}$ are determined by pinning of vortices by defects of the crystalline structure and by transparency of grain boundaries to current flow in polycrystals. Because the upper critical fields H_{c2} of many compounds can reach ~ 20 – 100 T, it is the high-field type-II superconductors, which are of prime interest for power and magnet applications. The current-carrying capability of these superconductors is determined by multiple mechanisms operating on different length scales: from the nanometer scales set by the size of vortex cores to the micrometer and larger scales, which define the scales of current flow in polycrystals with macroscopic materials defects. An optimum defect structure can be produced by appropriate materials treatments. For instance, J_c of polycrystalline high- T_c cuprates can be increased greatly by reducing the current-blocking effect of grain boundaries and incorporating artificial structures of oxide nanoprecipitates (Larbalestier et al., 2001; Maierov et al., 2009; Haugan et al., 2020).

Elementary pinning mechanisms

Under equilibrium conditions, magnetic flux penetrates into the bulk of a type-II superconductor above the lower critical field $H_{c1}(0) \simeq 10$ – 100 mT for many high-field materials. In a defect-free superconductor at $H > H_{c1}$ this magnetic flux exists in the form of a hexagonal lattice of quantized vortices. Each vortex can be regarded as a tube of radius of the London magnetic penetration depth $\lambda(T)$ in which screening currents circulate around a small non-superconducting core of radius $\xi(T)$, where the coherence length $\xi(0) \simeq \hbar v_F / 2\pi k_B T_c$ at $T = 0$ quantifies the size of the Cooper pairs, and v_F is the Fermi velocity (Tinkham, 1996). Vortices become energetically favorable at $H > H_{c1}$ if the Ginzburg-Landau parameter $\kappa = \lambda / \xi$ exceeds $2^{-1/2}$, as it happens in many superconducting compounds, especially such extreme type-II superconductors as Nb_3Sn or layered high- T_c cuprates or Fe-based superconductors (FBS) with $\kappa = 20$ – 100 . The magnetic flux produced by screening currents in a vortex equals the flux quantum $\phi_0 = 2 \times 10^{-15}$ Wb, so the vortex density B / ϕ_0 is proportional to the magnetic induction B . Bulk superconductivity is destroyed as the normal cores of vortices overlap at the upper critical field, $H_{c2}(T) = \phi_0 / 2\pi\mu_0\xi^2(T)$. In isotropic superconductors such as Nb-Ti and Nb_3Sn , vortex lines are continuous, but in highly anisotropic layered high- T_c compounds, such as $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_x$ and $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$, vortex lines break into stacks of weakly coupled “pancake” vortices whose circulating currents are mostly confined within the superconducting CuO_2 planes (Blatter et al., 1994). The current density $\mathbf{J}$ exerts the Lorentz force $\mathbf{f}_L = \phi_0[\mathbf{J} \times \hat{\mathbf{z}}]$ per unit length of the vortex line directed along the unit vector $\hat{\mathbf{z}}$, so that $\mathbf{f}_L$ is perpendicular to both $\mathbf{J}$ and $\hat{\mathbf{z}}$. Vortices can also exist in thin films of type-I superconductors in a perpendicular magnetic field if the film thickness d is much smaller than λ (Pearl, 1964; Blatter et al., 1994; Brandt, 1995). Here we mostly focus on bulk $J_c(H, T)$ in type-II superconductors with large κ and transverse sizes much larger than λ at magnetic fields well above H_{c1} . In this case $J_c(T, H)$ is not affected by demagnetizing effects which make H_{c1}

Fig. 1 A typical $J_c(T, H)$ surface which defines the region $J < J_c$ on the H-T diagram, where a type-II superconductor can carry weakly dissipative transport currents at electric fields $E < E_c$ with E_c depending on a particular application. Intersection of the $J_c(T, H)$ surface with the T-H plane defines the irreversibility field $H^*(T)$ at which a resistive transition to a flux flow state occurs.

dependent on the sample geometry, and the magnetic induction $B = \mu_0 H$ in a superconductor is directly proportional to the applied field H (Campbell and Evetts, 1972). In addition, the surface superconductivity can occur at $H_{c2} < H < H_{c3}$ for the field parallel to a perfect surface of a single crystal, where $H_{c3} \approx 1.7H_{c2}$ at $T \approx T_c$ (Tinkham, 1996). Yet for realistic imperfect surfaces in high- J_c superconductors in inclined magnetic fields, the third critical field H_{c3} is very close to H_{c2} so the surface superconductivity does not play a significant role in current transport controlled by pinning of vortices in the bulk.

Superconductors carry bulk weakly-dissipative (due to thermally-activated flux creep) currents caused by a vortex density gradient (or bending of vortices in thin films) described by the Maxwell equation $\nabla \times \mathbf{B} = \mu_0 \mathbf{J}$. This magnetic flux gradient can only be sustained by pinning of vortices by microstructural defects. Flux pinning is determined by local gains in the free energy of curvilinear vortices due to interactions of their normal cores and screening currents with these microstructural imperfections. Furthermore, a macroscopic current density $\mathbf{J}$ exerts the Lorentz force $\mathbf{F}_L = \mathbf{J} \times \mathbf{B}$ per unit volume of the magnetic flux. The critical current density $J_c(T, B)$ is then determined by the balance of the pinning and Lorentz forces $J_c(T, B)B = F_p(T, B)$, where F_p is the volume pinning force produced by the materials defects (Campbell and Evetts, 1972). Ideally, a type-II superconductor can carry any non-dissipative current density J smaller than J_c but if J exceeds J_c , a superconductor switches into a dissipative flux flow state in which vortices are driven by the Lorentz force. In any case, J_c cannot exceed the depairing current density J_d at which the transport current breaks the Cooper pairs:

$$J_c = \frac{\phi_0}{3^{3/2} \pi \mu_0 \lambda^2 \xi} \quad (1)$$

Here J_d is of the order of the current density circulating near the normal vortex, where $J_d(T) = J_d(0)(1 - T/T_c)^{3/2}$ at $T \approx T_c$.

Pinning defects can be classified by their spatial extent and by mechanisms of the elementary pinning forces f_p between vortices and defects (Campbell and Evetts, 1972; Blatter et al., 1994; Brandt, 1995). These defects can be either small pinning centers like non-superconducting precipitates and oxygen vacancies in high- T_c superconductors, or defects extended along vortex lines (grain boundaries, dislocations, columnar radiation tracks of nanorods). In turn, elementary pinning interactions can be due to either a short-range interaction of the vortex cores with point defects or a long-range magnetic interaction with extended planar defects. The core pinning results from a gain in the superconducting condensation energy at the core trapped by a defect, the strongest pinning force corresponding to defect sizes $\sim \xi$ (see Fig. 2).

Magnetic pinning results from the deformation of vortex screening currents near a planar defect on the scale $\sim \lambda$, as shown in Fig. 3. The magnetic pinning force $f(x) = \phi_0^2 / 4\pi \mu_0 \lambda^2 x$ can be rather strong if the distance x between the vortex and the defect is smaller than the interaction length $l = \phi_0 / 2\pi \mu_0 \lambda^2 J_b$. Here, $l < \lambda$ is the distance from the vortex core at which the circulating current density $J(x)$ equals the maximum current density J_b which can pass through the defect.

If the distance between the normal cores of bulk vortices and the defect is smaller than $l = \phi_0 / 2\pi \mu_0 \lambda^2 J_b$, vortices are attracted strongly to the defect. Vortices trapped by the defect may have no normal cores which turn into extended regions of length l along the defect in which the superconducting gap is not suppressed by circulating vortex currents. These elongated vortices on the defect have a highly anisotropic pinning force, which is maximum for $\mathbf{J}$ parallel to the defect and minimum for $\mathbf{J}$ perpendicular to the defect.

Identification of the most effective pinning defects in a particular material is a difficult task. Practical limits to flux pinning in high-field superconductors have been inferred from extensive studies of Nb-47%Ti, in which strong pinning by a dense ~ 20 – 25 vol% lamellar structure of metallic α -Ti ribbons ~ 1 nm (0.2ξ) thick can produce J_c that approaches 5–10% of J_d at zero field and 4.2 K (Larbalestier et al., 2001). The mechanism of flux pinning is also known for Nb₃Sn, in which J_c is determined by the magnetic interaction of vortices with Sn-deficient grain boundaries (Campbell and Evetts, 1972; Durrell et al., 2011). These materials have zero-field J_c values, which can exceed 10^{10} – 10^{11} A m⁻² at 4.2 K.

In high- T_c cuprates or Fe-based superconductors (FBS) the coherence length $\xi \simeq 1.5$ – 2 nm is so small that practically any common atomic-size defects such as vacancies or dislocations can pin vortices. The critical temperature of high- T_c superconductors is also sensitive to the carrier density, which, in turn, is determined by local non-stoichiometry, so that even a weak hole-depletion at crystalline defects may locally drive a high- T_c cuprate into an antiferromagnetic insulator. The proximity of the superconducting state in high- T_c cuprates or FBS to antiferromagnetic state, the d-wave pairing symmetry, the short in-plane coherence length $\xi(0) \simeq 1.5$ – 2 nm and the large Thomas-Fermi screening length $l_D \sim \xi(0)$, all combine to weaken superconductivity near crystal defects, such as impurities, dislocations, and grain boundaries, thus making them effective pinning centers (Gurevich, 2014). Typical parameters of some high- J_c superconductors with strong pinning are given in Table 1. These parameters can vary significantly, depending on concentrations of impurities and the materials treatments (Larbalestier et al., 2001; Hosono et al., 2018; Yao and Ma, 2021).

Single-vortex and collective pinning by point defects

Calculation of J_c requires summation of elementary pinning forces acting on flexible, strongly interacting vortex lines (Campbell and Evetts, 1972; Blatter et al., 1994; Brandt, 1995). The basic physics of the pinning force summation can be understood by evaluating J_c for a rigid straight vortex interacting with randomly distributed small non-superconducting precipitates in a film of thickness d (Fig. 2). If d is much greater than the mean spacing l_i between the precipitates, a vortex interacts with $N \sim r_p^2 dn_p$ pinning centers, adjusting its position so that the net force vanishes. Here r_p is the pinning interaction radius, and $n_p = l_i^{-3}$ is the density of pins. The transport current displaces the vortex from a local minimum in the pinning potential, so that elementary pinning forces do not compensate each other. The balance of the total pinning force from uncorrelated defects in the volume dr_p^2 against the Lorentz force, $f_p N^{1/2} \simeq d\phi_0 J_c$ yields

$$J_c \simeq \frac{1}{\phi_0} \sqrt{\frac{\gamma}{d}} \quad (2)$$

where $\gamma = f_p^2 r_p^2 n_p$ is the pinning parameter. As follows from Eq. (2), the critical current density $J_c(d)$ decreases as the film thickness increases. If $d \rightarrow \infty$, Eq. (2) gives $J_c = 0$ because the net pinning force of a rigid infinite straight vortex in a random pinning potential averages to zero.

Evaluation of bulk J_c must take into account bending of vortices near pinning centers. The effect of vortex elasticity can be understood using the following approach of a theory of weak collective pinning (Blatter et al., 1994; Brandt, 1995). Define a correlation length L_c along the vortex line by the relation $\langle u(L_c)u(0) \rangle = r_p^2$, where $\langle u(z)u(0) \rangle$ is a correlation function of pinning-induced transverse vortex displacements. The relative displacement of the ends of a vortex segment of length L_c exceeds the pinning interaction radius r_p , so a vortex may be regarded as an array of straight segments of length L_c pinned independently. Therefore, J_c can be evaluated from Eq. (2) with d replaced by L_c . In turn, L_c is evaluated by equating a characteristic pinning energy $\phi_0 J_c r_p$ and an elastic bending energy $\varepsilon(r_p/L_c)^2$, where $\varepsilon = \phi_0^2/4\pi\mu_0\lambda^2$ is the vortex line energy scale. The condition $\phi_0 J_c r_p \simeq \varepsilon(r_p/L_c)^2$ along with Eq. (2) at $d \simeq L_c$ yield:

$$J_c \simeq \frac{\gamma^2}{\phi_0 \varepsilon^{\frac{1}{3}} r_p^{\frac{1}{3}}}, L_c \simeq \frac{\varepsilon^{2/3} r_p^{2/3}}{\gamma^{1/3}} \quad (3)$$

Due to the collective interaction of a vortex with many pins, J_c increases as the line energy ε decreases because a softer vortex bends more easily to accommodate the pinning centers. Meanwhile, the correlation length L_c increases as the pinning parameter γ decreases, resulting in a “dimensional crossover” in films, from the two-dimensional pinning of rigid straight vortices at $d < L_c$ to the three-dimensional pinning of flexible vortices for $d > L_c$ (Blatter et al., 1994; Brandt, 1995).

A theory of weak collective pinning in strong fields $H \gg H_{c1}$ involves two characteristic spatial scales: the correlation length along the vortex lines $L_c(T, B, \gamma)$ and the correlation length $R_c(T, B, \gamma)$ perpendicular to the vortex lines. These lengths define the correlation volume $V_c = R_c^2 L_c$ - a mesoscopic region in which pinned vortices approximately maintain the positional hexagonal short-range order of the ideal flux line lattice. The positional long-range order of vortices is destroyed by pinning on scales larger than the correlation lengths L_c and R_c . The critical current density is then defined by the balance of the Lorentz force applied to the correlation volume, $B J_c V_c$ against the pinning force from spatially uncorrelated defects, $f_p N_c^{1/2}$, where $N_c = n_p V_c$. Hence,

$$J_c \sim \frac{f_p}{B R_c} \sqrt{\frac{n_p}{L_c}} \quad (4)$$

where both $L_c(T, B, \gamma)$ and $R_c(T, B, \gamma)$ depend not only on T and B , but also on the pinning parameter γ . The lengths $L_c(T, B, \gamma)$ and $R_c(T, B, \gamma)$ are determined from the conditions $\langle u(R_c, 0)u(0, 0) \rangle = r_p^2$ and $\langle u(0, L_c)u(0, 0) \rangle = r_p^2$, where the correlation function of vortex displacements $\langle u(r)u(0) \rangle$ is calculated using an elasticity theory for the vortex lattice. Depending on the relations between the pinning correlation lengths, the London penetration depth and the vortex spacing $a = (\phi_0/B)^{1/2}$, the collective pinning theory predicts a variety of behaviors of $L_c(T, B, \gamma)$ and $R_c(T, B, \gamma)$ which manifest themselves in different temperature and field dependencies of $J_c(T, B)$. For layered high- T_c superconductors, the pinning theory takes into account anisotropic elastic response of the vortex lattice. A crossover from a weak collective pinning to a strong single-vortex pinning occurs at lower B for which $R_c(T, B, \gamma)$ becomes smaller than the vortex spacing.

Unlike the collective pinning of vortices by many uncorrelated weak pins, interaction of a vortex with a strong pinning center can occur in a hysteretic manner because the elastic vortex line bends toward the pin and jumps into it once the spacing between the vortex and the pin gets smaller than a trapping distance which depends on the pin strength and the flux density B/ϕ_0 . The transition from the weak collective pinning to the hysteretic strong core pinning occurs if $k_L = f_p / \xi \bar{C} > 1$. Here k_L is the Labusch parameter which quantifies the strength of a single pin in terms of the ratio of the pinning force and bending elasticity of the vortex $\bar{C}$ (Blatter et al., 2004). At low fields $B \ll B_{c2}$, the vortex elasticity theory gives $\bar{C} \simeq 4(2\pi B/\phi_0)^{1/2} \varepsilon$ and the criterion of strong pinning $k_L > 1$ takes the form:

$$k_L \sim \frac{f_p \sqrt{\phi_0}}{4 \xi \varepsilon \sqrt{2\pi B}} > 1 \quad (5)$$

Eq. (5) shows that the strong hysteretic pinning tends to occur in the case of large pinning force, soft vortex line and low magnetic field. Increasing the density of pinning centers can push J_c toward the depairing limit, as it can indeed occur in optimized NbTi alloys or some of high- T_c cuprates. For instance, oxide nanoparticles of Y_2O_3 or $BaZrO_3$ incorporated into $YBa_2Cu_3O_{7-x}$ films can be tuned by varying the shape, size and distribution of oblate or prolate nanoprecipitates, self-assembled chains of nanoparticles or nanorods, typically spaced by 4–10 nm and being 2–4 nm in diameter to provide the strongest core pinning of vortices (Maierov et al., 2009; Haugan et al., 2020). The artificial pinning centers do enhance J_c at low field $B < 1$ tesla where $J_c(77K, 0) \approx (5-8) \times 10^{10} \text{ A m}^{-2}$ in $YBa_2Cu_3O_{7-x}$ films at self-field can approach 10–20% of J_d . Such “designer” pinning nanostructures also increase J_c at intermediate fields most relevant to magnet applications. For instance, the high values of $J_c(0, 77K) \simeq 2.7 \times 10^{10} \text{ A m}^{-2}$ and of $J_c(5T, 77K) \simeq 10^9 \text{ A m}^{-2}$ were observed on $YBa_2Cu_3O_{7-x}$ films with Y_2O_3 nanoparticles. Technological advances have resulted in high $J_c(0, 77K) \gtrsim 4 \times 10^{10} \text{ A m}^{-2}$ in FBS as well (Hosono et al., 2018; Yao and Ma, 2021).

Shown in Fig. 4 are two examples of strong pinning due to a dense array of spherical dielectric pins (a) and columnar pins with suppressed T_c (b). The very high J_c values in the cuprates and FBS mentioned above imply that pinning centers subdivide vortices into segments nearly as short as the vortex core diameter $2^{3/2} \xi$. To illustrate how far could J_c be increased, let us estimate J_c for strong core pinning by insulating nanoprecipitates of radius $r_0 \approx \xi$ which chop vortices into segments of length $l \ll \lambda$, as shown in Fig. 4A.

If the ends of each vortex segments are fixed by the strong pins, J_c is determined by the pin breaking mechanism due to cutting and reconnection of vortex semi-loops in the limit of $k_L \gg 1$ (Brandt, 1995). In this case vortex segments bow out under the action of flowing current, then reconnect and escape at the critical current density (Gurevich, 2014):

$$J_c \simeq \frac{\phi_0}{2\pi\mu_0\lambda^2\Gamma l} \ln\left(\frac{\Gamma l}{2\xi}\right) \left[1 - \frac{4\pi r_0^3}{3x_c l^3}\right] \quad (6)$$

Eq. (6) describes the limit of J_c in a uniaxial superconductor, where λ and ξ are the field penetration depth and the coherence length in the isotropic ab plane, and the anisotropy parameter $\Gamma = (m_c/m)^{1/2} > 1$ depends on the ratio of electron mass m_c along the c -axis to the mass m in the ab plane (typical values of Γ in $YBa_2Cu_3O_{7-x}$ and FBS range from 2 to 7). The factors in front of the brackets in Eq. (6) describe J_c due to pin breaking of a flexible vortex segment of length l . The factor in the brackets of Eq. (6) accounts for the reduction of the current-carrying cross section by randomly distributed dielectric pins, where the percolation threshold x_c varies

Fig. 4 Configurations of pinned curvilinear vortices (the cores of vortices of diameter $\approx 2\xi$ are shown by red) for: (A) strong pinning by dielectric nano precipitates, where the blue region of width $\approx \lambda$ in shows the spatial extend of superconducting currents (depicted by black arrows) circulating around the vortex cores. (B) pinning of fluctuating vortices by columnar defects with suppressed T_c .

from $1/2$ in the two-dimensional limit of layered materials $\Gamma \gg 1$ to $x_c \approx 2/3$ in the isotropic 3D limit ($\Gamma = 1$). Interplay of pinning and current blocking by pins results in a maximum $J_c(l)$ at $l_m \approx (16\pi/3x_c)^{1/3}r_0$ (Gurevich, 2014). This yields the optimal volume fraction of nanoprecipitates, $x_m \approx 9 - 12\%$ and the maximum $J_c \approx (0.2 - 0.3)J_d$. These numbers are close to the maximum values which have been achieved in NbTi (Larbalestier et al., 2001) or $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ with optimized pinning nanostructure (Haugan et al., 2020; Stangl et al., 2021). The maximum in $J_c(x)$ at an optimum volume fraction of pins has also been obtained in numerical simulations of the time-dependent Ginzburg-Landau equations for vortices pinned by metallic inclusions or regions with reduced T_c (Kwok et al., 2016).

Pinning and current blocking by extended defects

Pinning by extended defects, such as grain boundaries or columnar radiation defects shown in Figs. 3 and 4B, respectively differs from pinning by uncorrelated disorder, because a single extended defect parallel to $\mathbf{B}$ can pin a long vortex segment greater than the correlation length $L_c = \xi(J_d/J_c)^{1/2}$ of the collective pinning theory. Pinning by extended defects can be rather effective and result in high J_c values if the vortex is aligned with the defect. Indeed, a single vortex trapped by a cylindrical cavity of radius $r_0 \approx \xi$, has the pinning energy U_p of the order of the condensation energy of the vortex core $\phi_0^2/4\pi\mu_0\lambda^2$, yielding a very high $J_c \approx U_p/\xi\phi_0$ of the order of the depairing current density. This model has been used to describe experiments on irradiation of high- T_c superconductors with 1–10 GeV heavy ions (Pb, Au, Xe, etc.), which can produce 10–100 μm columnar tracks of about 5–10 nm in diameter comparable to ξ (see Fig. 4B). The areal density of columnar defects $n_\square$ is customary expressed in terms of the matching field $B_m = \phi_0 n_\square$ which typically ranges from 0.1 to 10 T for different irradiation conditions. For $B < B_m$, each vortex is trapped by a columnar defect, resulting in a significant enhancement of J_c in high- T_c superconducting films, as has been shown in many experiments. Columnar defects are most effective for vortices aligned with the defects, but J_c decreases strongly if the magnetic field is misaligned, so that J_c becomes very anisotropic with respect to the direction of $\mathbf{B}$.

Pinning by extended planar defects such as grain boundaries (GBs) in Nb_3Sn , or by thin α -Ti metallic ribbons in Nb—Ti can also result in high $J_c \sim 10^{10} - 10^{11} \text{ A m}^{-2}$ at 4.2 K in self field (see Table 1). Chemical nonstoichiometry, lattice disorder, strain, and charging effects associated with GBs cause local suppression of superconductivity in the cuprates and FBS. This can give rise to weakly linked GBs and magnetic granularity especially pronounced in high- T_c cuprates in which the critical current density through the grain boundaries J_b decreases exponentially as a function of the misorientation angle θ between the neighboring grains if $\theta > \theta_0 \approx 4 - 5^\circ$ (Hilgenkamp and Mannhart, 2002). As a result, J_b through GBs or thin α -Ti ribbons in Nb—Ti, is smaller than J_d in the bulk. It is the reduction of J_b as compared to J_d , which causes a strong magnetic and core interaction between a vortex and a planar defect, particularly, the radical change in the structure of the vortex core as it moves closer to the defect shown in Fig. 3. This results in two different types of vortices in polycrystals: vortices in the grains pinned by a long-range magnetic interaction with GBs and elongated vortices on GBs. Here J_c can be evaluated by balancing the total Lorentz force $F_p \sim BJ_c D^3$ in the grain of size $\sim D$

against the total pinning force proportional to the surface area of the grain $\sim D^2$. This yields a descending dependence of $J_c \propto D^{-1}$ on the grain size, as has been observed in Nb₃Sn with $1\mu\text{m} \lesssim D \lesssim 10\mu\text{m}$ (Durrell et al., 2011).

Grain boundaries can play a dual role in which they both pin vortices and block macroscopic current flow. In this case current loops can form in the grains if the critical current density due to pinning of vortices in the grains, is higher than the current density J_b , which can pass through GBs. This effect of magnetic granularity can limit global critical current density of superconducting polycrystals. In turn, it indicates that there is an optimum value of J_b , which maximizes J_c , because J_c vanishes in the two limiting cases of $J_b = J_d$ (no pinning, since GBs do not disturb currents circulating around vortices) and $J_b = 0$ (current cannot pass through grain boundaries). Calculation of the optimum J_c in addition to the summation of vortex pinning interactions, requires taking into account the geometry of the grains and microscopic mechanisms of current transport through the GB.

Current transport through GBs is particularly important for high- T_c polycrystals, for which the weak link behavior of high-angle GBs is one of the most serious current-limiting mechanisms. This behavior is due to rapid decrease of $J_b(\theta) = J_0 \exp(-\theta/\theta_0)$ with the misorientation angle θ and the resulting increase of the vortex core size, from ξ to $l(\theta) = \xi J_d/J_b(\theta)$ at $l(\theta) \lesssim \lambda$ to the Josephson core length $l(\theta) = [\xi J_d/J_b(\theta)]^{1/2}$ for $l(\theta) \gtrsim \lambda$. The extended core of the GB vortices leads to their weaker pinning force parallel to the boundary against the Lorentz force of the transport current flowing perpendicular to the boundary. As a result, the global J_c of polycrystals may be limited by depinning of a small fraction of vortices, which can move more easily along a network of GBs. This percolative motion of vortices along GBs is impeded by structural defects along GBs (such as facets, nanoprecipitates) and by magnetic pinning shear stress as the GB vortices move past more strongly pinned vortices in the grain (see Fig. 3). The significant reduction of J_b of GBs in high- T_c superconductors is due to the sensitivity of their critical temperature to a hole depletion, which can drive the high- T_c superconducting state into an antiferromagnetic insulator. The local hole depletion near GBs can be due to local oxygen nonstoichiometry, charging and strain effects produced by the crystalline dislocations which form the GB, or more macroscopic strain fields due to faceting (Hilgenkamp and Mannhart, 2002). The values of J_b can be improved by oxygen overdoping or local doping with appropriate impurities, such as Ca in YBa₂Cu₃O₇ or Sn in Nb₃Sn. The current-carrying capability of YBa₂Cu₃O₇ or FSB polycrystals can also be improved by depositing the superconducting films onto "biaxially textured" metallic substrates to eliminate the weakest high-angle GBs.

Global critical currents of superconductors

Multiple pinning mechanisms manifest themselves in different dependencies of the critical current density on T and B , which is often described by a scaling relation (Campbell and Evetts, 1972):

$$J_c(h) = J_{c0}(T) h^{-p} (1-h)^q \quad (7)$$

where $h(T) = H/H^*(T)$ is a reduced field, and $J_{c0}(T)$, p and q are the material-dependent parameters. For instance, Eq. (7) with $p = 0$ and $q = 1$ describes $J_c(B)$ in optimized Nb–Ti alloys, while $J_c(B)$ in Nb₃Sn is usually described by Eq. (7) with $p \approx 1/2$ and $q \approx 2$, consistent with pinning of vortices by grain boundaries. In high- T_c superconductors, $J_c(T, H)$ at elevated temperatures $T > 20 - 30$ K often exhibits an exponential field dependence $J_c(H) = J_{c0} \exp(-H/H_0)$, where the field $H_0(T)$ can be much smaller than $H_{c2}(T)$, especially in layered Bi₂Sr₂CaCu₂O_x. The irreversibility field $H^*(T)$ in layered high- T_c superconductors can be much smaller than $H_{c2}(T)$, whereas in low- T_c superconductors, such as Nb–Ti and Nb₃Sn, or "intermediate- T_c " compound MgB₂ with $T_c = 40$ K and some of the FBS, $H^*(T) \approx (0.8 - 0.9)H_{c2}(T)$ is not that different from $H_{c2}(T)$, as shown in Fig. 5 (see also Table 1). As a result, layered high- T_c cuprates Bi₂Sr₂CaCu₂O_x and Bi₂Sr₂Ca₂Cu₃O_x, despite their very high H_{c2} , can carry weakly dissipative currents at the liquid nitrogen temperature of 77 K only in a small part of the H – T diagram. This restriction is due to strong magnetic "flux creep" caused by thermally-activated hopping of flexible vortices between neighboring pinning positions at the current density J below J_c .

Vortex creep velocity $\mathbf{v}$ is parallel to the driving Lorentz force $[\mathbf{J} \times \mathbf{B}]$, causing the electric field $\mathbf{E} = [\mathbf{v} \times \mathbf{B}]$ directed along $\mathbf{J}$ (in isotropic materials). The E – J characteristic of a superconductor at $J < J_c$ has the form (Blatter et al., 1994):

$$E = E_c \exp \left[-\frac{U(J, T, B)}{k_B T} \right] \frac{J}{J_c} \quad (8)$$

where the Boltzmann factor $\exp(-U/k_B T)$ accounts for a fraction of depinned thermally-activated vortices resulting in the global flux motion. The flux creep activation energy $U(J, T, B)$ depends on the current density, which makes the E – J curve highly nonlinear at $J < J_c$. It is convenient to define the activation energy $U(J)$ in such a way that it vanishes at $J = J_c$ using one of the conventional approximations: (1) $U = (1 - J/J_c)U_0$, (2) $U = U_0 \ln[(J/J_c)^\mu - 1]$, (3) $U = U_0[(J/J_c)^\mu - 1]$, where $U_0(T, B)$ is an energy scale for thermally activated hopping of vortices. These models give an exponential increase of E with J at $J \approx J_c$, but different behaviors of $E(J)$ at $J \ll J_c$. Low- T_c superconductors typically have $U_0 \approx 500 - 1000$ K, whereas high- T_c superconductors can have considerably smaller $U_0 \approx 100 - 400$ K, since mobile pancake vortices on neighboring ab planes are weakly coupled due to the layered structures of these materials.

Because of weak dissipation at $J < J_c$, the critical current depends on the electric field E_c at which J_c is measured. Generally, J_c is defined as a crossover current density at which a resistive transition from an exponentially small $E(J)$ to a linear flux flow E – J curve occurs as shown in Fig. 6 (a conventional practical criterion of $E_c = 1 \mu\text{V cm}^{-1}$ is often used). The relation between J_c and J'_c measured at different electric fields E_c and E'_c can be obtained from Eq. (8) by linearizing the activation energy $U(J) = U_0(1 - J/J_c)$ near J_c :

Fig. 5 (A) Magnetic phase diagram of low- T_c superconductors, for which $H^*(T) \approx H_{c2}(T)$. (B) Magnetic phase diagram of high- T_c superconductors which cannot carry critical currents in a wide field range $H^*(T) < H < H_{c2}(T)$. Both cases (A) and (B) correspond to extreme type-II superconductors ($\kappa \gg 1$) for which the lower critical field $H_{c1} \ll H_{c2}$ is not shown.

Fig. 6 Broadening of the E-J characteristics as B increases. Here the green curve corresponds to B close to but below the irreversibility field B^* , while the FF line shows the Ohmic flux flow E-J characteristic at $B > B^*$. The dashed line shows the electric field criterion E_c at which J_c is defined.

$$J'_c = \left(1 + \frac{k_B T}{U_0} \ln \frac{E'_c}{E_c} \right) J_c \quad (9)$$

In low- T_c superconductors with $k_B T_c / U_0 \sim 10^{-2}$, the critical current density $J_c(E_c)$ varies only by a few percent in a practically accessible electric field window of $10 \text{ nV m}^{-1} < E < 100 \text{ mV m}^{-1}$. By contrast, high- T_c superconductors with $k_B T_c / U_0 \sim 10^{-1}$ have a broader resistive transition at $J \approx J_c$ and a larger difference between J_c and J'_c . The ratio $k_B T_c / U_0$ also defines the rate of slow time decay of currents in superconductors due to thermally-activated flux creep, $J(t) = J_c [1 - (k_B T / U_0) \ln(t/t_0)]$. The condition $U_0(H^*, T) \sim k_B T$ determines the irreversibility field $H^*(T)$ at which a nonlinear E-J curve turns into a nearly linear $E(J)$, as shown in Fig. 6. In layered high- T_c superconductors, such as $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_x$, the activation energy of pancake vortices is only a few times greater than $k_B T_c$. In this case of $H^*(T) \ll H_{c2}(T)$ at high temperatures pinning becomes ineffective in a significant part of the H-T diagram (Fig. 5B). In low- T_c superconductors, the dissipative region $H^* < H < H_{c2}$ shown in Fig. 5A is rather narrow, as discussed above (see also Table 1).

Thermal fluctuations of vortices give rise to the broadening of the resistive transition of a superconductor in a magnetic field and the region of $J_c = 0$ in Fig. 5. Such thermal depinning of vortices follows from the field and temperature dependencies of the

activation energy $U_0(T, B) = U_{00}(H_0/H)^z(1 - T/T_c)^s$ at $T \approx T_c$ and $J \rightarrow 0$, where the magnitudes of U_{00} and H_0 and the exponents z and s depend on particular pinning mechanisms (Blatter et al., 1994). For weak broadening, the width of the resistive transition ΔT can be evaluated from the condition $U_0(H, \Delta T) \sim k_B T_c$, which yields

$$\frac{\Delta T}{T_c} \simeq \left(\frac{k_B T_c}{U_{00}} \right)^{\frac{1}{s}} \left(\frac{H}{H_0} \right)^{\frac{z}{s}} \quad (10)$$

Hence, the width of the resistive transition increases with the magnetic field. For instance, if $z = 1$ and $s = 3/2$, Eq. (10) gives $\Delta T \propto H^{2/3}$. Thermal wandering of vortices also results in melting of the vortex lattice at $H < H_m(T) < H_{c2}(T)$. The melting field $H_m \simeq H^*$ is controlled by the dispersive line tension of the vortex $\varepsilon(k)$ for short wavelength bending distortions with the wave number $k \ll \lambda^{-1}$ (Blatter et al., 1994; Brandt, 1995):

$$\varepsilon_k \simeq \frac{\varepsilon}{\Gamma^2} \ln \frac{1}{k \xi_c}, \quad \varepsilon = \frac{\phi_0^2}{4\pi\mu_0\lambda^2} = \frac{\pi\hbar^2 n_s}{4m} \quad (11)$$

where m is the effective electron mass in the ab plane, ξ_c is the coherence length along the c -axis, $n_s(T)$ is the superfluid density, and $\Gamma = \lambda_c/\lambda$ is the anisotropy parameter, and λ_c is the magnetic penetration depth along the ab planes. As follows from Eq. (11), high anisotropy and low superfluid density n_s can strongly reduce the bending rigidity of a vortex. For instance, $\varepsilon_k \simeq 10^4$ K nm⁻¹ in Nb with $\lambda(0) \simeq 40$ nm, $\Gamma = 1$, while in YBa₂Cu₃O_{7-x} with $\lambda(77$ K) $\simeq 400$ nm, $\Gamma \approx 5$, we have $\varepsilon_k \simeq 5$ K nm⁻¹. Most FBS have $\varepsilon_k \simeq (200 - 500)(1 - T^2/T_c^2)$ K nm⁻¹, while the layered Bi-based cuprates have much lower $\varepsilon_k < 1$ K nm⁻¹ at 77 K. As a result, vortices in Nb form the rigid Abrikosov lattice, whereas in cuprates at 77 K thermal fluctuations can displace vortex segments by distances larger than the pin spacing thus smearing out the pinning potential and reducing $J_c(T, H)$. For instance, the vortex segments of length $\sim k_B T/\varepsilon \sim 10 - 100$ nm shown in Fig. 4A can hop and reconnect at neighboring pins, causing thermally-activated flux creep at $J < J_c$, no matter how strong the elementary pinning forces may be. The flux creep in arrays of columnar pins occurs via proliferation of vortex kinks between neighboring pins, as shown in Fig. 4B. In this case the flux creep rate can be reduced by splaying the columnar defects, which increases the vortex activation energy as compared to the parallel columnar pins (Maierov et al., 2009).

In addition to the multiscale pinning mechanisms, a global critical current density $J_c = I_c/A_{eff}$ of a conductor with a critical current I_c can be limited by macroscopic defects such as large second phase precipitates or microcracks which reduce an effective current-carrying cross section A_{eff} . Here, A_{eff} is determined by current percolation through arrays of large second-phase precipitates, colonies of high-angle grain boundaries, microcracks, and other inhomogeneities much greater than the spacing between vortices. This results in nonuniform current distributions in superconductors, which have been revealed by magneto-optical imaging or micro-Hall probes (Larbaestier et al., 2001). Macroscopic current flow in superconductors can be described by a nonlinear Maxwell equation $\nabla \cdot (J(\nabla\varphi)) = 0$ for the electric potential φ , where $E(J)$ is determined by Eq. (8). The strong nonlinearity of $E(J)$ at $J < J_c$ results in extended electric field hot spots near defects on scales much greater than the defect size b . Shown in Fig. 7 is an example of the spatial distribution of electric field around a microcrack of length b calculated for $E = E_c(J/J_c)^n$. In this case the electric field hot spot has the length $L_\perp \sim nb$ perpendicular to current flow and $L_\parallel \sim b\sqrt{n}$ parallel to current flow. For typical of low- T_c superconductors values of $n \simeq 30 - 50$, planar defects blocking only a few percent of the sample cross section can cause noticeable voltage drops on the conductor and reduce its current-carrying capability (Friesen and Gurevich, 2001).

Fig. 7 Spatial distribution of the electric field magnitude in a hot spot near a planar cut of length $b = 0.05w$ in a film of width w , calculated for the power-law E - J characteristic $E = E_c(J/J_c)^n$ with $n = 30$. Here, E_0 is the uniform field far away from the defect. Shown below the surface of $E(x, y)$ are the corresponding current streamlines in the film, where the red lines depict the boundaries of a flux jet emitted from the defect perpendicular to current flow.

Fig. 8 A coated conductor in which the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film is grown on a textured Ni alloyed substrate with a complex buffer layer structure, which enables replication of the low-angle grain structure of the substrate in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ and protects it from chemical contamination. The stabilizing layers of Ag and Cu on top of the 1–2 μm thick $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film provide protection of the conductor against thermal runaway. The superconducting current-carrying film takes only a few % of the conductor cross-section.

Strong pinning of vortices and high irreversibility field are not yet sufficient for applications which require long polycrystalline wires. One of the main issues for the cuprates (and to a lesser extent for FBS) is that grain boundaries between misoriented crystallites impede current flow. This is because the GB critical current density $J_b = J_0 \exp(-\theta/\theta_0)$ drops exponentially with the misorientation angle θ , as it was mentioned above. For the cuprates, $\theta_0 \approx 3 - 5^\circ$ so the spread of misorientation angles $\Delta\theta \approx 40^\circ$ in polycrystals can reduce J_b by 2–3 orders of magnitude. FBS also have weak-linked GBs but the larger values of $\theta_0 \approx 7 - 9^\circ$ in FBS make them less prone to the electromagnetic granularity, (Durrell et al., 2011; Hosono et al., 2018).

Discovered in 1988, the current-limiting GBs in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ bicrystals were immediately recognized as a serious obstacle for applications because, instead of flowing along the wire, current breaks into disconnected loops circulating in the grains. This problem has been addressed by the coated conductor technology in which a fraction of high-angle GBs with $\theta > 5 - 7^\circ$ is reduced by growing $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ films on textured metallic substrates. Fig. 8 shows an example of the coated conductor, which has made the idea of $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ “single crystal by the mile” a reality available for magnet dc applications. FBS coated conductors have also been developed (Hosono et al., 2018; Yao and Ma, 2021). While the coated conductors can carry high critical currents at 77 K, they utilize only a few % of the current-carrying cross-section, so J_c of the $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ film must be pushed to the limit by incorporating dense arrays of dielectric nanoprecipitates (Maierov et al., 2009; Haugan et al., 2020). However, the composite tapes shown in Fig. 8 have very high hysteretic remagnetization losses in alternating magnetic fields (Campbell and Evetts, 1972). For this reason, ac applications of superconductors in motors and generators require round composite wires in which twisted superconducting filaments are embedded in a highly conductive Cu or Ag normal matrix. This technology has been developed for multifilamentary Nb—Ti and Nb_3Sn round wires (Larbalestier et al., 2001), as well as for multifilamentary wires of the biaxially-textured $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_x$ in Ag matrix, and FBS wires (Yao and Ma, 2021).

Conclusion

Critical currents in superconductors are determined by multiscale pinning of strongly interacting curvilinear vortices by materials defects. Here non-superconducting defects can play a dual role by both pinning the vortices and blocking current flow, as it happens, for example, in Nb_3Sn in which pinning is caused by grain boundaries. As the volume fraction x of pinning centers increases, $J_c(x)$ of low- T_c superconductors can be pushed to a fundamental limit at an optimum value x_c determined by interplay of pinning and current blocking effects. The field range in which a superconductor can carry weakly-dissipative critical currents can be widened significantly by increasing H_{c2} by nonmagnetic impurities.

The physics of critical currents in anisotropic high- T_c cuprates and FBS with small Fermi energies, low superfluid densities and competing anti-ferromagnetic orders is further complicated by strong thermal fluctuations of vortices at high temperatures which can drastically reduce J_c and the irreversibility field. This manifests itself in different mechanisms of $J_c(T, H)$ at low and high temperatures. At $T \ll T_c$ the effect of vortex fluctuations is weak so J_c is determined by flux pinning in the same way as in

low- T_c superconductors and J_c in the cuprates can be increased greatly by incorporating strong pinning structure of oxide nanoprecipitates. However, as T increases, the effect of vortex fluctuations in layered high- T_c superconductors becomes dominant and the field region $H_{c1} < H < H^*(T)$, where they can carry weakly dissipative currents shrinks much faster than the decrease of $H_{c2}(T)$ with T . It turned out that the designer pinning nanostructures that increase J_c by several orders of magnitude at low temperatures in $\text{YBa}_2\text{Cu}_3\text{O}_{7-x}$ are less effective in increasing $H^*(T)$ at 77 K, although a combination of random nanoprecipitates and splayed pinning nanorods can reduce the effect of thermally-activated flux creep (Maiorov et al., 2009; Haugan et al., 2020). Understanding the ways by which pinning can be optimized to increase the irreversibility field in anisotropic high- T_c superconductors at 77 K remains an important outstanding problem.

Abstract

This chapter reviews some of the fundamental properties of high-temperature superconductors (HTSC), which include crystal structures, phase diagrams, superconducting properties, mechanisms, material processing and some newly developing superconductor. These would show a strong trait behavior of the high-temperature superconductivity that has been the subject of intensive study. It has received much attention due to its industrial applications.

Key points

- Crystal structures of most HTSCs can be obtained by stacking perovskite, rock salt and/or fluorite structure.
- The optimum T_c values above the liquid nitrogen temperature (77 K). Superconductivity happens when charge carriers overcome their mutual electrostatic repulsion, bind together into Cooper pairs, and condense into a single quantum state below a certain temperature.
- HTSCs are typical type-II superconductors by varying the external field H , at the lower critical field H_{c1} .
- Due to short coherence lengths and high anisotropy in cuprate superconductors, the vortex structures, and critical currents are different from those in conventional superconductors.
- Due to high-operating temperatures and reduced pinning compared to conventional superconductors, relaxation in HTSCs is very large.
- Thin films, bulk materials, tapes and wires, and coated conductors have received much attention

Introduction

In 1911, Kamerlingh Onnes discovered superconductivity in mercury with a transition temperature T_c of 4.2 K, at which the DC resistance of mercury dropped to zero. The second characteristic of a superconductor was its perfect diamagnetism, discovered by Meissner and Ochsenfeld in 1933. A theoretical understanding of superconductivity is based on the BCS microscopic theory, proposed by Bardeen, Cooper, and Schrieffer in 1957. Before 1986, the highest T_c in the now so-called low-temperature superconductors (LTSC) was found in Nb_3Ge (23 K). In 1986, Bednorz and Muller reported superconductivity in $(LaBa)_2CuO_4$ with a T_c of 35 K, in contrast to the previous record of 23 K in LTSC. Their discovery opened up the era of high-temperature superconductivity. The discovery of high-temperature superconductors (HTS) materials marked a significant milestone in the field of superconductivity, as it revealed the potential for superconductivity at higher temperatures than had previously been thought possible. Shortly after that, $YBa_2Cu_3O_7$ ($T_c = 90$ K), $Bi_2Sr_2Ca_2Cu_3O_{10}$ ($T_c = 110$ K), and $Tl_2Ba_2Ca_2Cu_3O_{10}$ ($T_c = 125$ K) were discovered. Since then, high-temperature superconductivity has been the subject of intensive study. In 2001, it was discovered that magnesium diboride (MgB_2) exhibits superconductivity with a T_c value of around 40 K, which is relatively high compared to most previously known superconductors. Since 2008, the Hideo Hosono group has been actively studying iron-chalcogenide and iron-pnictide superconductors. This article reviews some of the fundamental properties of high-temperature superconductors (HTSC) (Blatter et al., 1994; Campbell and Evetts, 1972; Cohen and Jensen, 1997; de Gennes, 1966; Ginsberg, 1989; Canfield and Crabtree, 2003; Biswal and Mohanta, 2021; Nagamatsu, 2001; Bednorz and Müller, 1986).

Overview

The year 1986 was a remarkable year for superconductivity physics. It was followed by a worldwide superconductivity research boom called the gold rush by superconducting physicists, which led to the discovery of seven series of HTSC materials with T_c above 90 K. The newly discovered HTSC have many exotic properties, such as small superconducting coherence length and anisotropic nature of the coherence length; anisotropic large penetration depth; anisotropic large energy gap; superconducting carriers are all holes; the existence of pseudo-energy gap; anisotropic and nonlinear characteristics of the normal state resistivity with temperature; nonlinear characteristics of the Hall coefficient with temperature; the parent is an antiferromagnetic structure, and the structure of the material is typical of the second class of superconductors with superconducting layers interspersed between charge bank phases. The material is a typical type II superconductor with a charge reservoir layer interspersed with superconducting layers.

Since the discovery of HTSC, the BCS theory has been used to explain them, but the T_c of HTSC have far exceeded those predicted by the theory, and the BCS theory has never given results on the phase anisotropy of superconductor parameters.

Superconducting physicists have proposed various models of strongly coupled superconducting matter (Fermi liquid model, non-Fermi liquid model) in an attempt to explain the mechanism of superconductivity in HTSC, but until now, no theory has been able to explain all the properties of HTSC. Although proposed by renowned physicists, the various theories that have been proposed to explain the mechanism of high-temperature superconductivity (HTSC) in materials like cuprates have not yet been universally accepted as definitive explanations for the phenomenon.

Although the BCS theory has obvious flaws, superconducting physicists still use it as a basis for studying and measuring the results of superconductivity studies. The reason is that the carriers of both LTSC and HTSC are Cooper electron pairs, and in this respect, they are the same. This is the basic premise of most superconducting physicists to acquiesce to the correctness of BCS theory. Therefore, the study of superconducting physics is of great theoretical significance and great practical significance (Huebener, 1970; Jin, 1993; Senoussi, 1992; Silver et al., 2002; Tinkham, 1996).

Numerous reviews have been written on the topic of high-temperature superconductors (HTS) materials, covering various aspects such as their properties, theory, and applications. Some of the most well-known and highly cited reviews in the field, which helped establish the field of HTS by presenting the first examples of materials that exhibit superconductivity at temperatures higher than previously thought possible (Anderson, 1987; Bednorz and Müller, 1988; Taillefer, 2010; Armitage and Greene, 2010).

Crystal structures

Crystal structures of most HTSCs can be obtained by stacking perovskite, rock salt and/or fluorite structure along the c -axis. As an example, Fig. 1 shows the orthorhombic $YBa_2Cu_3O_{7-\delta}$ unit cell. Other families of HTSCs can be constructed in a similar way. The CuO chains are unique to $YBa_2Cu_3O_{7-\delta}$; however, the most important features of the crystal structures of HTSCs are the two-dimensional copper oxide CuO_2 conduction planes, which are critical for high-temperature superconductivity. Carriers are doped into the CuO_2 conduction planes by transfer of charges resulting from the introduction of foreign ions, interstitial defects, and vacancies in structural blocks between two CuO_2 planes. These blocks are called charge reservoirs. The crystal structure of $YBa_2Cu_3O_{7-\delta}$ consists of stacked layers of CuO_2 planes and CuO chains, with Y and Ba ions located between these layers. The CuO_2 planes are the main sites of superconductivity, as they contain the Cu ions in a square planar arrangement that can form strong electron pairing. The CuO chains, on the other hand, act as charge reservoirs and can affect the doping level of the CuO_2 planes. In the orthorhombic phase of $YBa_2Cu_3O_{7-\delta}$, the CuO_2 planes are perpendicular to the crystallographic c -axis, and

Fig. 1 Crystal structure of orthorhombic $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$. Reproduced from Qin MJ and Dou SX (2005) Superconductors, high T_c . *Encyclopedia of Condensed Matter Physics*, 1st edn, vol. 6, pp. 112–120. Amsterdam: Elsevier.

the unit cell is elongated along the b -axis. The CuO chains run along the a -axis, and each CuO_2 plane is separated from the adjacent planes by one CuO chain. This arrangement of CuO_2 planes and CuO chains is often referred to as a “bilayer” structure, and it is one of the distinguishing features of the high-temperature superconductors.

Phase diagram

Depending on the temperature and the doping level, HTSCs demonstrate a wide variety of behaviors (see the phase diagram for hole-doped HTSCs in Fig. 2). Undoped HTSCs are antiferromagnetic Mott insulators with nearest-neighbor Cu^{2+} – Cu^{2+} antiferromagnetic exchange interaction in the CuO_2 planes. The Néel temperature T_N for the antiferromagnetic-to-paramagnetic transition decreases with increasing doping level. At a certain doping level, the antiferromagnetism vanishes and one enters the pseudogap or underdoped region. The normal-state properties in this region are significantly different from those of a Fermi liquid. Some of the most interesting behaviors of HTSCs are observed in this region. Superconductivity arises upon further doping. The transition temperature T_c first increases with increasing doping level, reaching a maximum T_c at an optimal doping level, then decreases and finally vanishes with further increases in doping (overdoped regime). The non-Fermi liquid region above the superconducting region is well described by the so-called marginal Fermi liquid (MFL) hypothesis.

Superconducting properties

The most unusual fundamental properties of HTSCs, compared to LTSCs, are high-transition temperature, short coherence length, and high anisotropy. The high anisotropy results from the layered structure shown in Fig. 1. A phenomenological description can be achieved by means of the anisotropic Ginzburg–Landau equation. A phenomenological description of high-temperature superconductors (HTSCs) can be achieved by means of the anisotropic Ginzburg–Landau (AGL) equation, which takes into account the anisotropic nature of these materials due to their layered crystal structure (Blatter et al., 1994). The AGL equation is a generalization of the GL equation, which is a widely used phenomenological model for describing the behavior of superconductors near the critical temperature. The AGL equation has been used to explain various superconducting properties of HTSCs, such as their anisotropic magnetic response and their nonlinear transport behavior (Brandt, 1995; Zhu and Ting, 2009).

Critical temperature T_c

The critical temperature (i.e., transition temperature from normal state to superconducting state) is one of the most important parameters characterizing superconductors. The optimum T_c values for some of the HTSCs are listed in Table 1. T_c values above the liquid nitrogen temperature (77 K) open the way for many applications. However, higher operating temperatures also introduce large thermal fluctuations in HTSCs. Based on the two principal properties of superconductors (zero-resistance and perfect diamagnetism), the usual methods to obtain T_c are to measure the resistance versus temperature curve $R(T)$ or the AC susceptibility versus temperature $\chi(T)$ curve. Other methods such as measurement of DC magnetization versus temperature $M(T)$ and heat capacity versus temperature $C(T)$ are also applied to measure T_c .

Coherence length ξ

It determines the distance over which the Cooper pairs are correlated. The short coherence lengths observed in HTSCs give rise to several unusual properties. Because the coherence length is much shorter than the penetration length, high-temperature cuprates are all type-II superconductors (see below). The short coherence length makes it very difficult to fabricate homogeneous high-temperature superconducting samples. Also associated with the short coherence length is the weak pinning of flux lines in HTSCs, compared with the pinning in LTSCs. To measure the coherence length, one usually needs to measure the upper critical fields $H_{c2}^{ab}(0)$ and $H_{c2}^c(0)$, then the coherence lengths can be derived according to the equations based on the anisotropic Ginzburg–Landau equation

$$\begin{aligned}\mu_0 H_{c2}^c(0) &= \Phi_0 / 2\pi \xi_{ab}^2(0) \\ \mu_0 H_{c2}^{ab}(0) &= \Phi_0 / 2\pi \xi_{ab}(0) \xi_c(0)\end{aligned}$$

Here, $H_{c2}^{ab}(0)$ and $H_{c2}^c(0)$ indicate the upper critical fields at $T = 0$ K for fields applied parallel to the ab -plane and the c -axis, respectively. Typical values for the coherence lengths are $\xi_{ab}(0) = 1.2$ – 1.6 nm, $\xi_c(0) = 0.15$ – 0.3 nm, for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$, $\xi_{ab}(0) = 2.7$ – 3.9 nm, $\xi_c(0) = 0.045$ – 1.6 nm for $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$, and $\xi_{ab}(0) = 2.1$ nm, $\xi_c(0) = 0.03$ nm for $\text{Tl}_2\text{Ba}_2\text{CaCu}_2\text{O}_{8+\delta}$.

Penetration depth λ

It determines the distance that the applied DC magnetic field can penetrate exponentially into the superconductor. There are several methods to measure the penetration depth, such as muon spin resonance (μSR), electron paramagnetic resonance (EPR), and the polarized neutron reflection techniques. The penetration depth can also be derived from measurements of susceptibility or magnetization on samples with dimensions similar to the penetration depth. Typical values for the penetration depths are for

Fig. 3 Schematic diagram of a single vortex when H is parallel to the ab -plane, showing the anisotropic penetration depth and coherence length. Reproduced from Qin MJ and Dou SX (2005) Superconductors, high T_c . *Encyclopedia of Condensed Matter Physics*, 1st edn, vol. 6, pp. 112–120. Amsterdam: Elsevier.

YBCO, the in-plane penetration depth $\lambda_{ab}(0)$ is in the range of 130–180 nm, while the out-of-plane penetration depth $\lambda_c(0)$ is in the range of 500–800 nm. In contrast, for BSCCO, $\lambda_{ab}(0)$ is greater than or equal to 3700 nm, while $\lambda_c(0)$ is in the range of 270–300 nm. Fig. 3 shows schematically the length scales (λ and ξ) of a vortex when the applied field is parallel to the ab -plane.

Critical fields

High-temperature cuprates are all type-II superconductors with three characteristic critical fields: the lower critical field H_{c1} , the upper critical field H_{c2} , and the thermodynamic critical field H_c (see Fig. 4). $\mu_0 H_c^2/2$ is the free-energy difference between the superconducting and normal states. When the applied field is lower than H_{c1} , the superconductor shows perfect diamagnetism (called the Meissner state); when the applied field is larger than H_{c1} but lower than H_{c2} , the applied field penetrates into the superconductor in the form of vortices (the so-called mixed state); when the applied field is larger than H_{c2} , the superconductor is forced into the normal state (see Fig. 4). As the upper critical fields at low temperatures are experimentally inaccessible, one is normally interested in H_{c2} close to T_c ; then using the dirty limit equation

Fig. 4 Phase diagram for a type-II superconductor. Reproduced from Qin MJ and Dou SX (2005) Superconductors, high T_c . *Encyclopedia of Condensed Matter Physics*, 1st edn, vol. 6, pp. 112–120. Amsterdam: Elsevier.

$$H_{c2}(0) = -0.693 \times \left(\frac{dH_{c2}}{dT} \right)_{T_c} T_c$$

to obtain $H_{c2}(0)$. Typical values for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ are $\mu_0 H_{c2}^{ab}(0) = 200$ T and $\mu_0 H_{c2}^c(0) = 40$ T. The lower critical field H_{c1} can be obtained from the virgin magnetization curves; typical values for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ at 4.2 K are $\mu_0 H_{c1}^c = 90$ mT, and $\mu_0 H_{c1}^{ab} = 20$ mT.

Pairing symmetry

The pairing symmetry is very important for the discovery of the pairing mechanism. After the discovery of HTSCs, experiments such as those involving the observation of magnetic flux states of a polycrystalline $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ ring, Andreev reflection, the Shapiro step of a Josephson junction, the high-resolution Bitter pattern technique, and Little–Parks oscillations have been performed to test whether Cooper pairing operates as in conventional superconductors. The results have confirmed electronic pairing in cuprate superconductors. In conventional superconductors, the phonon mediated electron–electron interaction gives rise to spin-singlet pairing with s -wave symmetry. However, the pairing symmetry in cuprate superconductors has been a controversial topic. Phase sensitive techniques (superconducting quantum interference device (SQUID)) interferometry, single Josephson junction modulation, thin film magnetometry, etc., combined with the refinement of several other symmetry-sensitive techniques (penetration depth, specific heat, thermal conductivity, angle-resolved photoemission, Raman scattering, nuclear magnetic resonance, nonlinear Meissner effect), have provided evidence in favor of d -wave symmetry pairing in cuprate superconductors. The energy gap, quasiparticle state, vortex state, and the surface and interfaces of d -wave superconductors are distinctly different from the s -wave case.

The pairing symmetry in high-temperature superconductors (HTSC) and low-temperature superconductors (LTSC) can be different. In conventional low-temperature superconductors, such as niobium or lead, the electron pairing is mainly due to electron-phonon interactions and the pairing symmetry is well described by the BCS theory, which predicts a s -wave pairing symmetry. This means that the electron pairs have no angular momentum and the energy gap in the electronic density of states is isotropic.

In contrast, the electron pairing mechanism in high-temperature superconductors is still a matter of debate, and several unconventional pairing symmetries have been proposed. Some high-temperature superconductors, such as cuprate superconductors, have a d -wave pairing symmetry, where the energy gap in the electronic density of states has nodes along the directions of the crystal lattice. Other high-temperature superconductors, such as iron-based superconductors, have different types of pairing symmetry, such as $s_{\pm}$, s_{++} , or d_{xy} -wave symmetry.

The difference in the pairing symmetry between HTSC and LTSC arises due to the different nature of the electron pairing mechanism. In HTSC, the electron pairing is believed to arise from the interplay of different competing orders, such as antiferromagnetism and superconductivity, and the symmetry of the superconducting order parameter is strongly influenced by these competing orders. In LTSC, on the other hand, the electron-phonon interaction is the dominant pairing mechanism, and the symmetry of the superconducting order parameter is determined by the properties of the phonon modes in the crystal lattice. Detailed discussions can be found in the references (Tsuei and Kirtley, 2000; Scalapino, 2012; Norman et al., 2011; Lee et al., 2006; Mazin et al., 2008).

Energy gap

The energy gap indicates the minimum energy required to excite a quasiparticle from a phase-coherent Cooper-pair condensate. The BCS theory predicts a universal ratio between the energy gap and the thermal energy $2\Delta(0)/k_B T_c = 3.53$, here $\Delta(0)$ is the energy gap at $T = 0$ K. For HTSCs, the energy gap can be determined from experiments such as single-electron tunneling, Andreev reflection, Raman scattering, photoemission spectra. Typical values for $\text{YBa}_2\text{Cu}_3\text{O}_{7-\delta}$ are $2\Delta_{ab}(0)/k_B T_c = 6-8$, $2\Delta_c(0)/k_B T_c = 3-3.5$; and for $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ are $2\Delta_{ab}(0)/k_B T_c = 8-11$, $2\Delta_c(0)/k_B T_c = 5-7$. For conventional superconductors, the Cooper pairs have an isotropic s -wave symmetry, which means that the energy gap is 2Δ everywhere in k -space (see Fig. 5). However, for a d -wave symmetry superconductor, in momentum space when $k_x = \pm k_y$, the energy gap is zero, which implies that it would change sign at $k_x = \pm k_y$ (see Fig. 5). Both properties will have important implications from both fundamental and applied points of view.

Fig. 5 The energy gap for s -wave superconductors (upper panel) and d -wave superconductors (lower panel). The s -wave symmetry has an isotropic value of 2Δ , while for a d -wave symmetry the gap vanishes and changes sign at $k_x = \pm k_y$. Reproduced from Qin MJ and Dou SX (2005) Superconductors, high T_c . *Encyclopedia of Condensed Matter Physics*, 1st edn, vol. 6, pp. 112–120. Amsterdam: Elsevier.

Type-II superconductivity

HTSCs have very short coherence lengths ξ and large penetration depths, so the Ginzburg–Landau parameter $\kappa = \lambda/\xi \gg 1$, and HTSCs are typical type-II superconductors. In this section, some of the properties in the mixed state are discussed (Ginsberg, 1989).

In particular, The Lawrence-Doniach model is an important theoretical tool for studying the behavior of type-II superconductors, including 2D superconductors, in the presence of a magnetic field (Lawrence and Doniach, 1971).

The LD model was first proposed by Lawrence and Doniach in 1971 and has since been used extensively to study the properties of type-II superconductors, including high-temperature superconductors (HTS) and 2D superconductors. The model takes into account the anisotropy of the superconductor, as well as the effects of the magnetic field on the electronic states and the order parameter of the superconductor.

In the LD model, the superconductor is described as a stack of many 2D layers, with the magnetic field applied perpendicular to the layers. Within each layer, the superconducting order parameter is assumed to vary smoothly along the direction parallel to the layers, while it is assumed to be uniform along the perpendicular direction. The LD model also takes into account the anisotropy of the superconductor, which arises from the fact that the coherence length (the characteristic length scale over which the superconducting order parameter varies) is different along different crystallographic directions.

The LD model can be used to calculate the irreversibility line, which is the boundary between the reversible and irreversible regimes of the superconductor in the presence of a magnetic field. Below the irreversibility line, the superconductor can expel the magnetic field and maintain its superconducting state. Above the irreversibility line, the superconductor is no longer able to expel the magnetic field and enters a mixed state, where vortices start to penetrate the superconducting layer.

Using the LD model, it is possible to calculate the distribution of vortices in the superconductor as a function of the applied magnetic field and the temperature. The model can also be used to calculate the critical current, which is the maximum current that can flow without destroying the superconducting state. In addition, the LD model can be used to study the effects of defects and impurities on the behavior of the superconductor, including the pinning of vortices and the enhancement of the critical current (Brandt, 1995; Campbell and Evetts, 1972; Kim and Beasley, 1975; Dew-Hughes, 1981; Blatter et al., 1994).

Vortex structure

Due to the high anisotropy of cuprate superconductors, the vortex structures are different from those in conventional superconductors. When the applied field is along the ab -plane, the screening current flows both along the ab -plane and along the c -axis. There exist insulating layers alternating with conduction layers along the c -axis, the current is the Josephson current in the insulating layers (see Fig. 6). When the applied field is parallel to the c -axis or at an angle to the c -axis, the vortices can be regarded as pancake vortices stacked along the c -axis (see Fig. 7). Each pancake vortex is located in one of the conduction planes. The pancake vortices in the neighboring layers are coupled by means of a Josephson current, which forms a Josephson vortex. The forces between pancake vortices in the conduction plane are repulsive, while the forces between pancake vortices in the neighboring layers are attractive. Depending on the temperature and the magnetic field, the vortex system can go through a 3D to 2D transition. The magnetic properties of 2D superconductors can be described by the Lawrence–Doniach (LD) model.

Irreversibility field

After the discovery of cuprate superconductors, it was soon reported that zero-field-cooled (ZFC) and field-cooled (FC) magnetization of La–Ba–Cu–O versus temperature at a fixed applied magnetic field can be separated into two regions. Below T_{irr} , ZFC and FC magnetization are different and irreversible, above T_{irr} , ZFC and FC magnetization are the same and reversible. T_{irr} is dependent on the magnetic field. $T_{irr}(H)$ or $H_{irr}(T)$ is called the irreversibility line. $H_{irr}(T)$ is lower than H_{c2} but larger than H_{c1} and separates the mixed state into two regions, a vortex liquid above $H_{irr}(T)$ and a vortex solid below $H_{irr}(T)$. The irreversibility line can also be obtained by hysteresis loop measurements and I – V characteristics measurements. Generally, the irreversibility line follows $1 - T_{irr}/T_{c0} = CH_{irr}^q$, with T_{c0} the zero-field transition temperature, and $\frac{1}{2} < q < \frac{3}{4}$, depending on different materials. The vortex system depends on three energy scales: the pinning potential E_{pin} , the thermal energy E_{th} and the vortex–vortex interaction energy E_{vv} . When the $E_{th} \approx E_{pin}$, the system reaches the reversible region (Ullmaier, 1975).

Critical currents and flux pinning

Due to short coherence lengths and high anisotropy in cuprate superconductors, critical currents are much more complicated than in conventional superconductors. For an anisotropic superconductor, three critical currents are defined depending on the direction of the applied magnetic field (see Fig. 8). Critical currents result from the interaction between vortices and crystal defects (pinning effect). Twin boundaries and screw dislocations in single crystal $YBa_2Cu_3O_{7-\delta}$ and Y_2BaCuO_5 phase, as well as stacking faults and dislocations in melt-textured-growth (MTG) $YBa_2Cu_3O_{7-\delta}$, have all been reported to act as pinning centers. Heavy ion and particle irradiation have also been used to enhance the critical current density in cuprate superconductors. Due to the short coherence length, point defects such as vacancies and substitution atoms may play an important role in cuprate superconductors (Huebener, 1970).

Critical current can be directly obtained from transport I – V measurements. From hysteresis loop measurements, the critical state model is used to derive the current density from the measured hysteresis loop,

$$J_{ab,c} = \frac{20\Delta M}{a(1 - a/3b)} \quad (H \parallel c)$$

Because a larger electric field criterion is used in transport measurement, it usually provides a larger critical current density than magnetic measurements. What it means is that when critical current density is measured using transport measurements (such as resistivity measurements), a larger electric field criterion is typically used compared to when it is measured using magnetic measurements. This is because the electric field criterion is related to the resistive behavior of the material, whereas the magnetic measurements are related to the pinning of vortices.

The use of a larger electric field criterion typically results in a higher critical current density because it allows for higher current densities to flow without causing the material to become resistive. Magnetic measurements, on the other hand, typically use lower field strengths, resulting in lower critical current densities because the magnetic field has a stronger effect on vortex pinning.

In polycrystalline samples, the current density across grains, called the intergrain critical current density, is very small, and shows the properties of a Josephson current. This is due to large angle grain boundaries in polycrystalline samples, and therefore these grain boundaries are called weak links. In order to have high critical current density, weak links should be avoided, by using, for example, melt-textured-growth (MTG) for $YBa_2Cu_3O_{7-\delta}$ bulk materials. Intragrain critical current densities up to 10^6 A cm $^{-2}$ at 77 K and 0 T has been reported for $YBa_2Cu_3O_{7-\delta}$ thin films.

Fig. 8 Schematic diagram showing the anisotropic critical current density in cuprate superconductors, when $H \parallel ab$ (upper panel) and $H \parallel c$ (lower panel). Reproduced from Qin MJ and Dou SX (2005) Superconductors, high T_c . *Encyclopedia of Condensed Matter Physics*, 1st edn, vol. 6, pp. 112–120. Amsterdam: Elsevier.

Flux creep

In conventional superconductors, the current density was observed to decrease logarithmically with time at fixed temperature and field, an effect called magnetic relaxation. Magnetic relaxation specifically refers to the behavior of the current density in a superconductor over time under the influence of a magnetic field. In conventional superconductors, the presence of magnetic vortices can disrupt the flow of current through the material, leading to a decrease in current density over time as vortices become thermally activated and move through the material. This logarithmic decrease in current density with time is known as magnetic relaxation (Brandt, 1995). This effect was explained by vortices thermally activated out of the pinning potential (flux creep) with the hopping frequency.

$$\nu = \nu_0 \exp \left[\frac{-U(j)}{k_B T} \right]$$

where ν_0 is the attempt frequency and $U(j)$ the effective activation energy depending linearly on the current density,

$$U(j) = U_0 \left(\frac{1-j}{j_{c0}} \right)$$

The current density decreases logarithmically with time as

$$j(t) = j_{c0} \left[1 - \left(\frac{k_B T}{U_0} \right) \ln \left(\frac{t}{t_0} \right) \right]$$

In cuprate superconductors, strong and nonlogarithmic relaxation has been observed (see Fig. 9). Due to high-operating temperatures and reduced pinning compared to conventional superconductors, relaxation in HTSCs is very large. Nonlogarithmic relaxation in HTSCs results from a nonlinear $U(j)$ relationship. A logarithmic $U(j)$ relationship has been proposed to account for the experimental results:

$$U(j) = U_0 \log \left(\frac{j_c}{j} \right)$$

On the other hand, according to the vortex glass theory, the $U(j)$ relationship is

$$U(j) = \left(\frac{U_0}{\mu} \right) \left[\left(\frac{j_c}{j} \right)^\mu - 1 \right]$$

Fig. 9 Magnetic relaxation of a melt-texture-growth (MTG) YBCO sample at $H_{||c} = 2$ T and 70 K, showing nonlogarithmic relaxation. Reproduced from Qin MJ and Dou SX (2005) Superconductors, high T_c . *Encyclopedia of Condensed Matter Physics*, 1st edn, vol. 6, pp. 112–120. Amsterdam: Elsevier.

Here, the exponent μ depends on the dimensionality of the vortex system.

Magnetic relaxation measurements have been extensively performed on HTSCs to study the flux dynamics. The purpose is to determine the effective pinning potential $U(j)$ and compare it with theoretical predictions. Several methods such as the Maley method, the generalized inversion scheme, and dynamic relaxation and the AC susceptibility technique have been developed for this purpose. However, because too many parameters are used in theoretical predictions, it is impossible to unambiguously determine the effective activation energy from experiments. Most results in this area are not conclusive (Clem and Coffey, 1990; Matsuda and Tsuneto, 1989; Yeshurun et al., 1996; Kes et al., 1991).

Melting of the vortex lattice

Thermal fluctuations in HTSCs are much more important than in conventional superconductors. According to the Lindemann melting criterion, as the displacement away from the ideal configuration by thermal fluctuation reaches 10–30% of the average flux-line separation, melting transition from vortex solid-to-vortex liquid (shear modulus equal to zero) might take place. The curve $T_m(H)$ in the H – T phase diagram at which the flux lattice melts is called the melting line. It has been suggested that in clean samples with negligible pinning the vortex solid-to-vortex liquid transition is expected to be of the first order, while static disorders drive the transition to the second order as in the vortex glass theory. Evidence for a first-order melting transition comes from a jump in the reversible magnetization, changes in latent heat, a frequency-independent peak in the AC susceptibility and a sharp, hysteretic, resistive transition. However, the effect of static disorders and their dimensionality on the order of transition is unclear as yet (Wördenweber, 1999).

Mixed-state phase diagram

For a type-II superconductor, by varying the external field H , at the lower critical field H_{c1} , a phase transition from the Meissner phase to the Abrikosov phase (or mixed phase) takes place. The basic unit of the mixed state is the vortex, which contains a flux quantum given by $\Phi_0 = ch/2e = 2.07 \times 10^{-7} \text{ G cm}^2$, penetrating the system and forming a perfect triangular crystal (the Abrikosov lattice). At the upper critical field H_{c2} , the system is forced to undergo a second phase transition to the normal state. The simple phase diagram shown in Fig. 4 neglects disorders and thermal fluctuations, which is very serious in cuprate superconductors due to higher operating temperatures. When thermal fluctuations are taken into account, the first modification applied to the phase diagram ought to be the inclusion of the “water-like” melting phenomenon discussed above. In clean systems, the melting curve stretches from H_{c1} up to H_{c2} (see Fig. 10). In case of disordered systems, the melting line terminates at much lower fields (characterized by the first-order transition). In practice, one is often far from the critical fields, leading to the unified phase diagram in Fig. 11. Then, one has to discriminate between a sharp first-order phase transition at lower fields separating Bragg glass and vortex liquid and a more continuous second-order-like transition at higher fields separating vortex glass and vortex liquid.

Normal-state properties

Properties in the normal state of cuprate superconductors have been found to be very useful for the understanding of the mechanism of high-temperature superconductivity. These properties include resistivity, Hall coefficient, thermopower, magnetism, thermal conductivity, and optical properties. Although superconducting properties of cuprate superconductors are quite similar to those of conventional superconductors, the normal-state properties are unique. As an example, some general features for normal-state resistivity are listed: (1) the resistivity is anisotropic with the c -axis resistivity ρ_c two orders of magnitude larger than the in-plane resistivity ρ_{ab} , (2) ρ_{ab} shows metallic behavior, but ρ_c mostly shows semiconductor behavior. (3) ρ_{ab} is close to linear in T , which is the most striking normal-state property of cuprate superconductors. Theoretical explanations for these behaviors and other unique behaviors observed in optical and thermal properties remain controversial.

Experimental methods

Here are some examples of experimental methods and studies that are commonly used to determine scaling lengths and energies in HTSCs, along with corresponding references: Angle-resolved photoemission spectroscopy (ARPES): This technique is used to measure the electronic structure of a material, including the superconducting gap, which can provide information about the

coherence length and energy scale of the superconducting state (Damascelli et al., 2003; Norman, 1998). Scanning tunneling microscopy and spectroscopy (STM/STS): These techniques can be used to directly probe the local density of states and the superconducting gap in a material, which can provide information about the coherence length and energy scale of the superconducting state (Fisher et al., 2011; McElroy et al., 2005). Microwave surface impedance measurements: These measurements can be used to determine the superfluid density of a material, which can provide information about the penetration depth and energy scale of the superconducting state (Prozorov et al., 1998). Magnetic field dependence of critical current density (J_c): This measurement can be used to determine the magnetic field penetration depth and coherence length of a material, which are related to the energy scale and correlation length of the superconducting state (Brandt, 1995).

Magnesium diboride (MgB₂)

MgB₂ has superior properties such as the thermodynamic and transport properties, the isotope effect, band structures, promising critical current density, the ability of doping effect and pressure effect. However, after the discovery of its superconducting properties in 2001 by Akimitsu's group, it has been a promising compound in superconductivity applications. MgB₂ is competitive among high-temperature superconductors (HTS) because it has fascinating advantages such as simple crystal structure, low material cost and small anisotropy. As it is, MgB₂ has opened our eyes to previously unrealized possibilities for electron–phonon superconductivity. Higher transition temperatures and other compounds now occupy our dreams and novel basic phenomena such as two-gap superconductivity drive theory and experiments in new directions. Unlike the still controversial cuprates, the physical picture and quantitative theoretical description for MgB₂ are now available. The behavior near T_c is determined by the large 2D gap, which produces a step as expected for a conventional one-gap superconductor (Canfield and Crabtree, 2003).

Iron-based superconductor

In recent years, Fe-based superconductors have found a lot of unanticipated surprises. These types of superconductors consist of different classes of iron materials, like pnictides, chalcogenides, intermetallics and oxides. Although each group has its own features, some most important properties of the materials are quite similar. In the study of superconductors of iron-chalcogenides and iron-pnictides, Hideo Hosono group is active since 2008 (Hosono et al., 2015). Distinctly HTSC copper oxide superconductors, from magnetic properties, structures and superconducting behavior, the T_c of Fe-based superconductors is as much as 55 K, the electron-phonon interaction is quite too weak. Fe-based superconductors can be spread into a number of types of substances consisting of 3 households of iron-based superconductors such as '1111' system RFeAsO (R: the rare earth element) consisting of LaFeAsO, SmFeAsO, PrFeAsO etc. '111' type LiFeAs, NaFeAs & LiFeP etc., '122' type BaFe₂As₂SrFe₂As₂ or LaFe₂As₂ etc. The iron-based superconductors give a wonderful likelihood of understanding unconventional superconductivity which could be useful to explain the mechanism of High- T_c superconductivity, and also the implementation of iron-based superconductors, especially in tapes and wires that can be fabricated for industry applications (Biswal and Mohanta, 2021).

Thin films

YBa₂Cu₃O_{7-x}(YBCO) thin films are the most studied high-temperature superconducting thin films. Critical current densities up to 10^6 A cm⁻² have been achieved in high-quality YBCO thin films, making them very attractive for applications. There are, in general, two main methods for fabricating high-temperature superconducting thin films: in situ or ex situ film growth. In situ films are oxygen-treated before they are removed from the growth chamber, and therefore are superconducting after growth. Ex situ thin films must be annealed in an oxygen-rich environment after growth to be superconducting. Nearly every growth technique has been tried on high-temperature superconducting thin films, including evaporation, pulsed laser deposition (PLD), metal organic chemical vapor deposition (MOCVD), and on-axis and off-axis sputtering. Every technique has its merits and drawbacks, details of which can be found in the references. The search for substrate materials is an active research area. High-quality YBCO thin films have been deposited on LaAlO₃, SrTiO₃, MgO, YSZ, etc. BiSrCaCuO and TlBaCaCuO thin films have also been extensively studied. However, it is very difficult to obtain single-phase BiSrCaCuO thin films, while Tl is very toxic, creating problems in fabricating TlBaCaCuO thin films. The main application of superconducting thin films is in the area of superconducting electronics.

Bulk materials

Many large-scale applications such as flywheel energy-storage systems need HTSCs in bulk form. Sintered YBCO polycrystalline samples used to have very low critical current densities (100–1000 A cm⁻²), which was attributed to weak links at grain boundaries, such as structural disorder at grain boundaries, chemical or structural variations at grain boundaries and non-superconducting materials along grain boundaries, as well as microcracking. Texture processing has been developed as a means to avoid or minimize the effects of weak links in polycrystalline YBCO. The initial success with bulks was due to the melt-textured-growth (MTG) process,

which enhanced the critical current density two to three orders of magnitude over that of sintered materials. Several modified MTC methods were developed later in order to further enhance the critical current density. These include the quench-and-melt-growth (QMG) process, the melt-powder-melt-growth (MPMG) process, the power-melting process (PMP), the floating-zone-melt (FZM) process, the platinum-doped melt-growth (PDMG) process, and the horizontal Bridgman method.

Tapes and wires

The majority of the work on superconducting tapes and wires focuses on the $\text{Bi}_2\text{Sr}_2\text{Ca}_2\text{Cu}_3\text{O}_{10-x}$ (BSCCO) system. The reasons are that the BSCCO system has a higher critical current at high magnetic fields, and that the BSCCO system does not suffer from the weak link problems of YBCO. The fabrication of BSCCO tapes and wires is usually carried out by means of the so-called oxide power-in-tube (OPIT) method. The powder is packed in a tube (typically Ag), then the Ag tube is drawn to a small diameter and rolled into a flat tape. The tape is then annealed, re-rolled and re-annealed again to obtain the best superconducting properties. Critical current densities up to 7000 A cm^{-2} for a 650 m long and 19-filament-rolled tape have been achieved. Tapes and wires are widely used in applications such as motors and generators, magnet, transformers, and transmission lines.

Coated conductors

Coated conductors are YBCO thin films deposited onto polycrystalline substrates. The films are biaxially textured, thus overcoming the phenomenon of weak links. This has been achieved by preparing a biaxially textured buffer layer, upon which the YBCO film is subsequently grown epitaxially. The two most advanced techniques are the ion beam-assisted deposition (IBAD) process, and the rolling-assisted biaxially textured substrate (RABiTS) process. In addition, inclined substrate deposition (ISD) has also emerged as a promising method for the fabrication of YBCO conductors. The coated conductors potentially have a performance superior to the first generation bismuth-based HTS compounds (BSCCO), such as high current carrying capacities, strong mechanical properties, and extraordinary magnetic field tolerances. Recently, it has been demonstrated that current densities up to 10^6 A cm^{-2} have been achieved in conductors prepared by coating thick films of YBCO onto flexible metallic substrates. One of the biggest hurdles to widespread application of YBCO-coated conductor tape is developing a manufacturing process that will produce it in long lengths and at prices competitive to copper for applications such as motors, generators, transmission cables, and other power systems.

Conclusion

In Summary, Superconductivity occurs when charge carriers form Cooper pairs and enter a single quantum state at a temperature below a threshold. In conventional superconductors, phonons are responsible for pairing, while in HTSCs, the mechanism is controversial. Several theories have been proposed, but no comprehensive theory accounts for all experimental observations. HTS materials have unique properties, such as the ability to carry large amounts of electrical current with zero resistance, operate at higher temperatures, and possess unique mechanical and thermal properties that offer potential for various applications. Continued research and development in this field will likely lead to further discoveries and new applications of these materials. The production techniques, performance, and low price are crucial in realizing practical and cheap cryogenic systems. Nanomaterials and superconducting physics are both branches of condensed matter physics, and a breakthrough in either discipline will have a chain reaction leading to rapid development.

Certainly. Here are some examples of novel and unconventional functionalities that HTS materials have brought compared to LTS materials:

1. HTS materials have very high critical current densities, allowing them to operate at much higher magnetic fields than LTS materials. This makes them attractive for applications such as magnets for MRI machines, fusion reactors, and particle accelerators.
2. HTS materials can be fabricated as thin films and coatings using techniques such as pulsed laser deposition, sputtering, and metal-organic deposition. This allows for the development of high-performance, flexible, and lightweight superconducting materials for various technological applications.
3. The unique properties of HTS materials have opened up new possibilities for developing novel superconducting devices and systems, such as superconducting microwave filters and resonators, superconducting power transmission lines, and superconducting fault current limiters.
4. HTS materials exhibit improved stability compared to LTS materials, particularly at high magnetic fields and temperatures. This makes them more suitable for practical applications where stability is critical.
5. There have been recent reports of HTS materials exhibiting superconductivity at or near room temperature, which could revolutionize the field of superconductivity and lead to a wide range of new applications.

Overall, HTS materials have brought a range of novel and unconventional functionalities that have expanded the field of superconductivity and opened up new possibilities for technological applications. However, they also present unique challenges and require continued research and development to fully realize their potential.

Abstract

Since the discovery in 1986, enormous research efforts have remarkably advanced our understanding of the high- T_c cuprates, but some important issues remain unresolved. Primarily strong electronic correlations lead to superconductivity with unconventional d -wave pairing, which emerges upon doping into the Mott insulating state. The temperature-doping phase diagram of the cuprates is extremely complex with several orders or incipient orders showing up. In particular, the pseudogap and strange-metal regimes encompass a wide region and appear to be home not only to the superconducting order but also to various spin and charge orders.

Key points

- The cuprate phase diagrams are much more complex than previously anticipated as a standard one with antiferromagnetic, superconducting, Fermi liquid phases, and pseudogap regime as main players. The generic phase diagram further incorporates short-range and incipient spin, charge, and superconducting orders as well as strange metal regime.
- The short-range spin order –spin-density-wave (SDW)- in the heavily underdoped region is replaced by the short-range charge order –charge-density-wave (CDW)- as doping proceeds, and simultaneously the d -wave superconducting order sets in.
- The doping dependence of the superconducting transition temperature T_c shows a dome and T_c is controlled mainly by the superfluid density rather than the superconducting gap magnitude.
- Above T_c , there is a regime of precursory pairing -superconductivity without global phase coherence- in which the superconducting gap is almost unaffected. The precursory pairing state is a two-dimensional superconducting state without interlayer phase coherence and also a vortex liquid state under magnetic fields.
- The pseudogap regime is a playground for these orders and possibly other hidden orders, being intertwined and sometimes competing with one another. However, its origin remains a puzzle, and whether or not the doping, at which the pseudogap collapses, is a quantum critical point continues to be a matter of intense debate.
- Both SDW and CDW fluctuations are pervasively present over the entire superconducting doping range, extending to temperatures far above T_c with large energy scales of a few tenths of eV.
- The stripe order observed specific to the La-based cuprates is a showcase displaying how the spin-charge-pairing orders are intertwined and may thus be viewed as a pseudogap regime in a different appearance.

- The hole overdoped regime is not a simple Fermi liquid as formerly thought. On passing through the optimal doping, the superfluid density starts to decrease despite that the normal-state carrier density continues to increase. Its reason is currently under hot debate.
- Above the pseudogap temperature in the underdoped region and above T_c in the overdoped region, the metallic state is recognized as a strange or bad metal. In this regime, the charge transport properties are difficult to reconcile with the notion of quasiparticles in the Landau-Boltzmann theory. The mechanism of the charge transport in this regime is at present difficult to be elucidated. However, apparently this regime is a home to both pseudogap and Fermi liquid, and hence is a key to resolve the high- T_c problems.

Introduction

The copper oxides (cuprates) stand out in their high T_c values, and are only family that achieved T_c well above the liquid nitrogen temperature at ambient pressure. High- T_c superconductivity (HTS) in the cuprates was discovered by Bednorz and Müller in 1986. Even after intensive research efforts over 35 years unraveling the mechanism of HTS and searching for higher T_c continue to be two grand challenges in condensed matter sciences. The understanding of the high- T_c cuprate materials and their electronic properties has substantially advanced. A consensus that has been achieved is that primarily repulsive electron-electron interactions lead to superconductivity with unprecedentedly high T_c as well as unconventional Cooper pairs. The common structural unit, CuO_2 plane, is an insulator driven by strong electron-electron repulsive interaction (a Mott insulator). Unconventional superconductivity emerges upon doping into the insulating CuO_2 plane.

Another consensus is that characterization of the “normal” state, in particular, the pseudogap regime above T_c and the ‘strange metal’ regime at elevated temperatures in the phase diagram, is indispensable for unraveling the mechanism. Recent progress is the discovery of a “plethora of orders” with broken-symmetry and their fluctuations that manifest in the pseudogap regime. In this chapter, starting from an overview of how the cuprates are unique in their electronic structure and what are necessary ingredients for high T_c , are described the current understanding and the key issues of the doping (p)-temperature (T) phase diagram and relationship of various emergent orders with the superconducting order.

Overview

Uniqueness of the cuprates

High-temperature superconductivity with T_c well exceeding the liquid-nitrogen temperature (77 K) is found only in a class of materials whose basic structural unit is the surprisingly simple CuO_2 plane, layers of Cu and O arranged in a square lattice (see Figs. 1A and B). The neighboring CuO_2 planes are separated by so-called “charge reservoir” layers/blocks. Roles of the charge reservoir layers are to supply carriers to the CuO_2 planes by chemical substitution and/or by adding or reducing oxygen atoms, and to stabilize the cuprate crystal structure the negatively charged CuO_2 planes, $[\text{Cu}^{2+}\text{O}^{2-}_2]^{2-}$, are neutralized by forming an alternating stack with positively charged layers.

The undoped CuO_2 plane is a “Mott” or charge transfer (CT) insulator due to the strong Coulomb repulsion ($U \sim 6\text{--}8$ eV) between electrons on the $3d$ orbitals of Cu atoms. As schematically depicted, the energy gap is actually created between occupied $\text{O}2p$ band and empty $\text{Cu}3d$ band (the upper Hubbard band), so it is called as a charge-transfer (CT) gap E_{CT} (Fig. 1C). A Cu^{2+} ion has 9 electrons in the $3d$ orbitals and it is four-fold coordinated in a CuO_2 square lattice. As a consequence, the uppermost $3d$ orbital is $3d_{x^2-y^2}$ and occupied by a single electron (hole) as depicted in Fig. 1D. This lone electron (hole) is localized on Cu due to strong Coulomb repulsion, leaving a magnetic moment associated with the $S = 1/2$ spin quantum number. The Cu spins align antiferromagnetically on the CuO_2 plane in the undoped cuprate due to superexchange interaction J between neighboring Cu spins via an intervening O atom. The singly occupied Cu $3d_{x^2-y^2}$ level form a single band by the hybridization with the $\text{O}2p_x$ and $\text{O}2p_y$ states which would be half-full, if the Coulomb repulsion were not strong. Since Cu is at the end of the $3d$ transition metal series in the periodic table, the energies of $\text{Cu}3d$ states are incidentally close to those of the $\text{O}2p$ states as schematically shown. This makes the CT energy gap small, $E_{\text{CT}} = 1.5\text{--}2.0$ eV, compared with that in other transition-metal oxide. In particular, the wavefunction of $3d_{x^2-y^2}$ has large overlap with that of $\text{O}2p_x$ and $\text{O}2p_y$. The overlap integral or hopping matrix element t_{pd} is large, $\sim 0.3\text{--}0.4$ eV, leading to strong hybridization between the two.

The unique features of the cuprates and widely anticipated necessary conditions for high T_c are thus summarized as.

- (1) layer structure,
- (2) strong electronic correlations,
- (3) $S = 1/2$ spin state,
- (4) accidental degeneracy between $\text{Cu}3d$ and $\text{O}2p$ energies.

No other materials so far known have all these features simultaneously.

Fig. 1 (A) Crystal structures (schematic) of a representative high- T_c cuprate, $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$, and (B) the CuO_2 plane. (C) Schematic energy scheme of the insulating undoped cuprate showing a strong electronic correlation (U) on a Cu atom and a charge-transfer (CT) energy gap between $\text{O}2p$ and $\text{Cu}3d$ upper Hubbard band. (D) Orbital configuration of a CuO_2 unit showing relevant $\text{Cu}3d_{x^2-y^2}$ and $\text{O}2p_\sigma$ ($\sigma = x$ or y) orbitals, both being strongly hybridized.

The large overlap integral t_{pd} and the closeness of $3d$ and $2p$ levels, i.e., small CT gap, give rise to strong covalent nature of the Cu-O bond as well as to the unusually large spin superexchange interaction $J \sim t_{pd}^4/E_{CT}^3 \sim 0.15$ eV. The strong covalent bond makes the phonon frequency corresponding to the modulations of the Cu-O bond length (or bond angle) fairly high ($\hbar\Omega_0 \sim 0.07$ eV). The large energy scales of the charge (t_{pd}), spin (J), and phonon (Ω_0) related excitations are probably sources of strong pairing interactions and hence high T_c .

The layer structure leads to their highly two-dimensional (2D) character of the electronic state, and $S = 1/2$, the minimal spin quantum number, makes the spin fluctuation maximal. Because of these two, the otherwise very stable AF order (due to large J) becomes fragile against doping and raising temperature. Finally, the strong correlations favor unconventional pairing with nodes in the superconducting (SC) gap.

Temperature-doping phase diagram

In the 'standard' phase diagram (Orenstein and Millis, 2000) sketched in Fig. 2, antiferromagnetic (AF), superconducting (SC), and overdoped 'Fermi liquid' (FL) phases evolve with increase of doping (either electrons or holes). In the case of the electron-doped

Fig. 2 'Standard' phase diagram of electron- and hole-doped cuprates. With increase of doping, the antiferromagnetic phase transforms to the superconducting (SC) and then the Fermi liquid (FL) phase. A broad antiferromagnetic phase and a wide pseudogap regime are characteristic of electron- and hole doped cuprates, respectively.

cuprates, $\text{Nd}_{2-x}\text{Ce}_x\text{CuO}_4$ ($T_c^{\text{max}} = 25$ K) and so-called infinite-layer $\text{Sr}_{1-x}\text{La}_x\text{CuO}_2$ ($T_c^{\text{max}} = 40$ K), the AF phase is robust, while the SC phase is realized in a narrow doping range. The superconducting T_c values are distinctly low, although the superconductivity is conceived to be unconventional d -wave. On the other hand, in the phase diagram of the hole doped cuprates pseudogap (PG) regime prevails, and at high temperatures there is a “strange” metal regime in which the in-plane (current flowing along the CuO_2 planes) resistivity continues to increase linearly with T without showing a tendency for saturation.

Key issues

This chapter focuses on the phase diagram of the hole-doped cuprates. They are genuine high- T_c superconductors, and the understanding of their phase diagram is believed to be a key to unravel the mechanism of high- T_c superconductivity. Recent progress in various advanced spectroscopies has revealed that the phase diagram, shown in Fig. 3, is much more complicated than previously anticipated, and incorporates various orders (broken symmetries). It turns out that various ordering phenomena including various types of fluctuating orders take place in the pseudogap regime.

Spin order

Local $S = 1/2$ spin magnetic moments on Cu atoms align antiferromagnetically in the CuO_2 plane (the Néel order with ordering wavevector $\mathbf{Q}_{\text{AF}} = (0.5, 0.5)$ in the unit of $2\pi/a$) by the huge superexchange interaction J between neighboring Cu spins. The long-range antiferromagnetic (AF) order sets on at $T = T_N$ (~ 300 K for the parent compound) in a second order phase transition. The ordering temperature T_N is much lower than $J \sim 1500$ K because the AF order is subject to strong thermal and quantum mechanical fluctuations. The former arises from the two-dimensionality, while the latter from the $S = 1/2$ minimal spin quantum number. This phase is essentially Mott insulating and the insulating gap is a $\text{Cu}3d\text{-O}2p$ charge-transfer (CT) gap, $E_{\text{CT}} = 1.5\text{--}2.0$ eV, arising from the strong on-Cu site electronic repulsion.

The long-range AF order is quite fragile against hole doping. The long-range AF order collapses upon doping holes of about 0.02 per Cu atom, but spin order persists as a short-range spin-density-wave (SDW) order which is incommensurate with the underlying lattice. Different from the long-range AF order, the short-range SDW freezes gradually with lowering temperature. The onset temperature of SDW is low $T_{\text{SDW}} < 50$ K. The spin correlation length is short but finite at all temperatures showing slow dynamics with a wide distribution of the relaxation rates, characterized as a spin-glass. For further doping, typically $p = 0.05\text{--}0.08$, the short-range SDW disappears, and the superconducting order sets on.

Spin fluctuations

Even after SDW disappears, dynamical spin fluctuations remain up to very high dopings. The spin excitation spectrum or the dispersion of spin excitations is similar in all cuprate families. The undoped cuprates with commensurate AF order show spin wave (magnon) dispersion from zero at a wavevector $(0.5, 0.5)$ in the unit of $2\pi/a$ up to a high energy of ~ 0.3 eV reflecting extremely large superexchange coupling J (100–150 meV). With hole doping, the magnons evolve into heavily damped excitations (called paramagnons) dispersing upward from a characteristic energy ω_r (Fong et al., 2000). Below ω_r , the excitations are less damped with downward dispersion toward incommensurate spin ordering wavevectors $(0.5 \pm \delta_s)$, $\delta_s = Q_{\text{SDW}}$. This hourglass-shaped dispersion of spin excitations is in common among the cuprate families.

Fig. 3 Generic temperature (T) - doping (p) phase diagram of the hole-doped cuprates. Various orders emerge below the T^* line. The onset of short-range charge order is indicated by red square, and below T_{SDW} (blue dashed curve) a short-range spin order exists. Signatures of precursory superconductivity are observed within the subdome shadowed by pale green.

The low-energy spin excitations are gapless, but when p exceeds 0.08 (around the onset of SC), a gap in the spin excitations (spin gap) starts to develop and simultaneously a short-range charge order (charge-density-wave) appears. The spin fluctuations or dynamic antiferromagnetic spin correlations are still intact up to high doping region (Dean et al., 2013). These dynamic spin fluctuations in cuprates are much stronger than in conventional metals,

Unconventional superconductivity

As regards the SC phase, there are many differences from conventional superconductors:

- 1) T_c is unprecedentedly high.
- 2) The SC gap function, $\Delta(\mathbf{k})$, has an unconventional d -wave symmetry (Tsuei and Kirtley, 2000), strongly momentum ($\mathbf{k}$) dependent, $2\Delta(\mathbf{k}) = \Delta_0 [\cos(k_x a) - \cos(k_y a)]$, a being the in-plane lattice constant. It changes sign on the Fermi surface (FS) and hence vanishing at some $\mathbf{k}$'s (gap nodes). The gap nodes are along the Brillouin-zone diagonal, and the gap magnitude is maximum (called as "antinodes") at the zone edges, $(\pm 0.5, 0)$ and $(0, \pm 0.5)$ in the unit of $2\pi/a$, as schematically depicted in Fig. 4.
- 3) The SC transition temperature T_c as a function of hole doping p , $T_c(p)$, shows non-monotonic variation with p , consisting of a dome, starting to rise from p_1 , showing a weak cusp (or plateau) at $p \sim 1/8$ for $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ ($\text{YBa}_2\text{Cu}_3\text{O}_{7-y}$), reaching a maximum at so-called "optimal" doping p_{opt} and then dropping to zero at p_2 . In real cuprate samples both ends, p_1 and p_2 , of the T_c dome are not sharp boundaries. Due to unavoidable inhomogeneity in the local dopant density, the superconducting state near the ends is granular in nature and hence the SC transition is percolative. On the other hand, the amplitude of $\Delta(\mathbf{k})$, typically 30–40 meV, is only weakly dependent on p , so there appears no direct link between T_c and Δ_0 (unlike in conventional s -wave SC $\Delta \sim 2k_B T_c$).
- 4) T_c appears to have a more intimate link to the superfluid density. The superfluid density or SC phase stiffness ρ_s ($\sim n_s/m^*$, n_s and m^* being Cooper pair density and carrier effective mass, respectively) in cuprates is by orders of magnitude smaller than that in conventional superconductors. T_c increases linearly with ρ_s in the underdoped region (Uemura et al., 1989), stops increasing or saturates around p_{opt} and then starts to decrease beyond p_{opt} . ρ_s is, in principle, a very basic quantity that characterizes the SC order, but in conventional superconductors ρ_s is so high that it does not explicitly appear in the superconducting properties. By contrast, ρ_s in the high- T_c cuprates is anomalously low, and consequently shows up as a relevant parameter in various properties including T_c .

Precursor pairing

As the superfluid density or the phase stiffness ρ_s is low and the materials are effectively two-dimensional (2D), the cuprates are expected to subject to strong SC phase fluctuations (Emery and Kivelson, 1995). The best circumstantial evidence for a precursory SC (or phase-disordered SC) state comes from diamagnetism at high magnetic fields (Li et al., 2010) that is observed from T_c up to T_{pair} (about $1.5 T_c$). Though weak compared to full Meissner screening, it is still large compared to that of simple metals. Compelling evidence is in the temperature evolution of the gap itself; The SC gap observed by angle-resolved photoemission spectroscopy (ARPES) does not collapse at T_c but persists up to temperature about T_{pair} (Chen et al., 2019). The large Nernst effect observed in the temperature range between T_c and T_{pair} (Xu et al., 2000) is also a signature of precursory SC. It cannot be ascribed to the motion of normal-state charge carriers, but most likely arises from moving vortices in the SC condensate which destroy the global phase coherence without affecting the SC gap. Such Nernst effect is reminiscent of genuine 2D superconductors where the pairs establish a long-range coherence through a Berezinskii-Kosterlitz-Thouless (BKT) transition. The BKT transition is driven by

Fig. 4 Variation of the magnitude and sign of the d -wave superconducting gap in the first Brillouin zone. The Fermi surface for the optimally doped cuprate is superposed on the gap map. The gap nodes are along the zone-diagonal and the gap magnitude is maximal at the zone edges (antinodes).

proliferation of vortices. These signatures differ from superconducting fluctuations observed in classic superconductors which are fluctuations of the amplitude of the pair wavefunction and observed only in the close vicinity of T_c . In the case of cuprates, the amplitude remains finite above T_c and the fluctuations are primarily of the phase.

Magnetic field penetrates a type-II superconductor as vortices, and the vortices form a regular array (vortex solid). For a conventional superconductor the vortex lattice is collectively pinned by impurities or defects, so that the full diamagnetic response (Meissner effect) and the zero-resistivity disappears only when the magnetic field (B) reaches the upper critical field H_{c2} . By contrast, the vortex lattice in cuprates easily melt by increasing B to a field value $H_m(T)$ much smaller than H_{c2} . The observed large Nernst signal and the diamagnetic response above T_c indicate that a vortex liquid state exists even above T_c up to the temperature T_{pair} (Li et al., 2013). The persistence of the vortex liquid is thought to be due to the small interlayer phase stiffness in conjunction with the extremely large pairing energy scale. The former makes the interlayer SC phase coherence to be destroyed at a weak field comparable to the lower critical field H_{c1} , and the latter does the pairing amplitude $|\Psi|$ robust against raising T above T_c and against increasing B . Therefore, the vortex liquid phase is regarded as a manifestation of the 2D precursory pairing phase.

Charge order

Charge order (CO) or periodic spatial modulations of charge density (charge density wave, CDW). CO was first discovered in the La-based cuprates with the K_2NiF_4 structure (La214), $\text{La}_{2-x-y}\text{Nd}_y\text{Sr}_x\text{CuO}_4$ and $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$ (LBCO) at $x \sim 1/8$ as *stripe order* (Tranquada et al., 1995). The stripe charge order is a long-range order and coexists with the spin order. Recently, CDW has been discovered for almost all the cuprate families, typically $\text{YBa}_2\text{Cu}_3\text{O}_{7-y}$ (YBCO). In contrast to the stripe order, the short-range SDW order is not seen in YBCO in the doping range larger than 0.08 where the CDW order is observed. In this regime, spin excitations are gapped, while charge excitations are gapless.

The x-ray scattering experiments find a gradual onset of static and short-range CDW order at $T_{\text{CDW}} = 100\text{--}160$ K (Chang et al., 2012; Ghiringhelli et al., 2012). The incommensurate CDW has ordering vectors (Q_{CDW}) always along one of the Cu-O bond directions and hence unidirectional. Q_{CDW} is typically $0.25\text{--}0.3$ ($2\pi/a$), depending on material, doping as well as temperature. The CDW correlation length (ξ) estimated from the x-ray scattering peak width is about a few CDW periods, $\sim 15\text{--}25$ Å in many cuprate families. The microscopic observation of CDW in $\text{Bi}_2\text{Sr}_2\text{CaCu}_2\text{O}_{8+\delta}$ (Bi2212) by scanning-tunneling-spectroscopy (STS) has confirmed a unidirectional charge order (Kohsaka et al., 2007). In the direction perpendicular to the planes, the CDW has almost no correlation between neighboring layers, so it is confined within a CuO_2 plane, i.e., two-dimensional (2D). Experimental probes with longer time scales, such as nuclear-magnetic-resonance (NMR) (Wu et al., 2011), have confirmed that the short-range charge order is almost static, presumably due to pinning of correlated charge fluctuations by lattice disorder.

As a function of doping, the onset temperature T_{CDW} forms another dome between 0.08 and 0.18 with a maximum at $p \sim 1/8$ (Blanco-Canosa et al., 2014). Intriguingly, the onset temperature of the precursory pairing, T_{pair} , is comparable with T_{CDW} , and both show similar doping dependence. Both T_{CDW} and T_{pair} -subdome share nearly the same doping region within the superconducting T_c dome. T_{CDW} is highest near $p = 1/8$ where T_c shows a shallow dip or a plateau but T_{pair} is also highest. This indicates that CDW in cuprates is not a mere competitor of d -SC, but it is obviously “intertwined” with d -SC in marked contrast to the known CDW systems in which CDW and SC are competing and mutually exclusive orders.

CDW fluctuations

The recent extensive study of the resonant-inelastic-x-ray-scattering (RIXS) of $\text{NdBa}_2\text{Cu}_3\text{O}_{7-y}$ (and YBCO) has observed a broad peak, being centered near Q_{CDW} , attributable to charge density fluctuations signal arising from dynamic CDW correlations. The dynamic CDW correlations are found to exist over a wide region of the $T - p$ phase diagram (Arpaia et al., 2019). They persist up to temperatures well above T_{CDW} and even above the PG temperature T^* , and are thought to be precursor to the low-temperature quasi-static CDW. The precursor CDW is also two-dimensional, and temperature independent. The in-plane CDW correlation length ξ_{CDW} is extremely short, only one CDW period or less and T -independent. Along the doping-axis, they are observed from the lowest end ($p \sim 0.08$) of the quasi-static CDW to even the overdoped region ($p \sim 0.2$). Notably, the integrated scattering intensity (spectral weight) of the fluctuating CDW is by about an order of magnitude larger than that of the quasi-static CDW, indicating that only a small fraction of the total CDW correlations condenses into the quasi-static low-temperature CDW order due possibly to pinning by lattice disorder.

There are two possibilities on the mechanism of the formation of charge order in cuprates: One is the real-space mechanism based on the strong electronic correlations and the other is the momentum-space mechanism such as Fermi surface nesting assisted by electron-phonon coupling for the classical CDW systems. The universal dynamic CDW correlations with high-temperature and high-energy scales point toward the strong electronic correlations as a primary driving force of the cuprate charge order.

Now that both AF (or SDW) and CDW fluctuations are pervasively present in the entire SC doping region, an important question to be answered in future is which fluctuations of either spin or charge or both orders drive the high- T_c superconductivity. The spectrum of CDW fluctuations covers a wide momentum region and extends to the energy scale of $0.2\text{--}0.3$ eV, comparable to that of the hourglass-shaped spin fluctuations. It is theoretically argued that if the spin fluctuations contributed to the pair formation as a glue, the charge fluctuations would play either as an independent glue to enhance SC order or as a pair breaker for d -wave pairing.

Pseudogap regime

This, sometimes called as an underdoped regime, is the most mysterious regime in the phase diagram, and the understanding its origin and nature is considered to be a key to resolve the high- T_c mechanism: The pseudogap (PG) regime covers a wide T - p area of the phase diagram ($T < T^*$ and $p < \sim p_{\text{opt}}$) in which various spectroscopies indicate a suppression of low energy electronic excitations below the pseudogap temperature T^* . There remain puzzles in the origin of PG, but it is a playground for various types of ordering phenomena, SDW, CDW as well as d -SC. As described above, the quasistatic incommensurate spin and charge short-range orders as well as precursory pairing develop within the PG regime.

In the PG regime below the T^* line various spectroscopies show a suppression of low energy electronic excitations (Homes et al., 1993). An energy scale of the PG is typically ~ 0.1 eV, significantly larger than the SC gap scale (typically 30–40 meV). PG opens in the portion of the Fermi surface near antinodes (the Brillouin-zone edges, $\mathbf{k} = (0.5, 0)$ and $(0, 0.5)$ in the unit of $2\pi/a$), leaving behind the Fermi arc centered at nodes on which gapless and coherent quasiparticles reside (Marshall et al., 1996). This anisotropic gap gives rise to a dramatic change in various properties at T^* . For example, the c -axis (directed perpendicular to the CuO_2 planes) resistivity shows an upturn below T^* as T is decreased like an insulator, whereas the in-plane resistivity drops at T^* associated with a drop in the carrier scattering rate.

The structure of the pseudogap in momentum space was directly mapped by ARPES experiments. In the temperature range between T^* and T_c , the charge excitations are gapless on the Fermi arc and a gap is present near antinodes (Ding et al., 1996; Loeser et al., 1996), which crudely mimics the d -wave SC gap (the pseudogap is apparent only in the “antinodal” regions at which the d -wave gap is largest). In the SC phase, PG coexists with d -wave SC gap in non-trivial manner. Below T_c d -wave SC gap starts to open on the Fermi arc, whereas PG in the antinodal region remain almost unchanged with magnitude larger than inferred d -wave gap extrapolated from the Fermi arc region (Tanaka et al., 2006).

Given that there is no evidence that the SC gap energy scale is diminished by the presence of PG, it is likely that PG is also home to the SC pairing correlation. Hence, PG is not necessarily a competing order of d -SC, but appears to be home to various orders including SC.

It continues to be a matter of debate whether the T^* line indicates a phase transition or a crossover. T^* rapidly decreases with increasing p , and the $T^*(p)$ line appears to penetrate the T_c dome, extrapolating to a hole density $p^* \sim 0.18$. If PG is a phase associated with some broken symmetry, then p^* would be a quantum critical point (QCP) at which a continuous phase transition takes place at zero temperature. CDW with broken translational symmetry is a candidate for the PG phase, but in the phase diagram the CDW order exists in the doping region narrower than that of PG and T_{CDW} is significantly lower than T^* .

There are experimental observations that are suggestive of broken symmetries below T^* other than translational symmetry associated with SDW and CDW. Spin-flip neutron scattering experiments (Fauqu  et al., 2006) indicate intra-unit cell time-reversal symmetry breaking ($q = 0$ staggered magnetic order), supposedly arising from counter-circulating orbital current inside the unit cell (Varma, 2006). Scanning-electron-tunneling spectroscopy (STS) also suggests a rotational symmetry breaking inside the unit cell ($q = 0$ nematic order) (Lawler et al., 2010). A signature of rotational symmetry breaking was also detected by thermodynamic probes. However, the intra-unit-cell ($q = 0$) orders cannot open a gap by themselves, and even if a gap opens with a help of some secondary order, it is difficult to account for such a large PG energy scale.

The presence of a QCP at p^* is also challenged by the most recent experiments (Cooper et al., 2009; Chen et al., 2019). Thus, the origin of the PG has yet been identified. Apart from the presence or otherwise of QCP, the PG regime is a playground for various types of $q \neq 0$ short-range orders including SDW, CDW and precursory pairing (or pair-density-wave) which can, in principle, create a gap. Since they are intertwined to each other, it is possible to speculate that the observed pseudogap is a spin-charge-pair entangled gap (Loret et al., 2019).

Stripe order

The stripe order in cuprates is a unique spin and charge order and a visible case of an intertwined charge, spin, and electron-pair orders. A plausible structure of the static spin-charge stripe order, illustrated in Fig. 5A, is a periodic array of charge stripes with antiferromagnetically ordered spin stripes between neighboring charge stripes (Tranquada et al., 1995). The periods of the spin and charge stripe array are typically $8a$ and $4a$, respectively, for the doping $x = 1/8$ in LBCO. The periods change with changing doping, but the charge order wavevector Q_{CO} of the charge stripes is locked to that (Q_{SO}) of the spin stripes with $Q_{\text{CO}} = 2Q_{\text{SO}}$. In the materials showing stripe order a structural phase transition from high-temperature-orthorhombic (HTO) to low-temperature-tetragonal (LTT) occurs before the stripe order starts to develop. The LTT lattice deformation acts as a pinning potential for the charge stripes. Matching to the LTT structure, the orientation of the stripes changes by 90° as one moves from one layer to the next, forming three-dimensional (3D) spin-charge stripe order. The magnitude of the ordering wavevector Q_{CO} of the charge stripes increases with doping as expected in a real space picture, that is, Q_{CO} is determined by a distance between charge stripes with the same hole concentration. Though special to La214 cuprates, the stripe order helps in understanding the interplay between SDW, CDW and SC orders (including precursory SC) all of which are important ingredients for shaping the ‘generic’ phase diagram of the cuprates, in particular, the PG regime.

The spin stripe order onsets at lower temperature, T_{SO} , than the onset of the charge stripe order, T_{CO} . Triggered by the LTT lattice deformation, segregation of doped holes starts to form charge stripes at T_{CO} . After the holes are fully segregated on the charge stripes, the AF ordered domains, or spin stripe order, are created between neighboring charge stripes at T_{SO} . Distinct from the insulating

Fig. 5 (A) A schematic structure of spin-charge stripe order. (B) Phase diagram of the stripe-ordered $\text{La}_{2-x}\text{Ba}_x\text{CuO}_4$. At $x = 1/8$ the stripe order is most stable. The onset of charge (spin) stripe is indicated by T_{CO} (T_{SO}). The formation of charge stripe is triggered by the structural phase transition at T_{LTT} , and the onset of spin stripe coincides with the onset ($T_{\text{c}}^{2\text{D}}$) of two-dimensional superconductivity. The three-dimensional superconductivity is suppressed at $x = 1/8$, but soon recovers with increase or decrease of x from $1/8$.

stripes in other doped Mott-insulators such as nickelates and cobaltites. The cuprate stripe ordered state stays metallic and even superconducting. While the stripe order suppresses bulk (three-dimensional, 3D) superconductivity, there is growing evidence that pairing, in a form distinct from the spatially uniform d -wave SC order, is taking place (Li et al., 2007). This superconducting order can be viewed as a spatially modulated SC order, pair-density-wave (PDW). Given that the stripe orientation varies 90° on moving from one layer to the next, and if SC order between one charge stripe and the next is antiphase within a layer, the Josephson coupling between layers is completely frustrated (Himeda et al., 2002; Berg et al., 2007). This interlayer decoupling isolates each superconducting CuO_2 plane and thus a two-dimensional superconducting state (2D-SC), likely PDW, emerges in the stripe-ordered state.

The phase diagram of LBCO is shown in Fig. 5B. For $x = 1/8$ ($T_{\text{CO}} = 55$ K) the onset of 2D pairing correlation within the CuO_2 plane coincides with the onset of the spin-stripe order ($T_{\text{SO}} \sim 40$ K). At T_{SO} a steep drop of the in-plane resistivity (ρ_{ab}) is observed whereas the c -axis resistivity (ρ_c) continues to increase. With further cooling below ~ 16 K, ρ_{ab} becomes vanishingly small but ρ_c is still finite, evidencing that the pairs establish a long-range coherence within a plane - 2D superconductivity order - through a Berezinskii-Kosterlitz-Thouless (BKT) transition observed at $T_{\text{BKT}} \sim 16$ K (Li et al., 2007). The pronounced nonlinear current-voltage characteristics observed below 16 K yields further support the 2D-SC.

Different from other cuprate families, the coexisting spin stripe order in the La214 family is a prerequisite for realizing the supposed PDW state with antiphase SC order between neighboring charge stripes within a layer. In an array of antiphase charge stripes the pair wavefunction can get zero where the amplitude of spin stripe is maximum which matches the empirical rule that static SC order avoids spatial overlap with static AF order. This might be the reason why the onset of 2D-SC coincides with T_{SO} .

To achieve three-dimensional superconductivity (3D-SC), it is necessary to lock together the phases of the superconducting CuO_2 planes via interlayer Josephson coupling. When the 2D superconducting correlations within the plane sufficiently develop, even a small interlayer Josephson coupling is enough to realize 3D-SC. The frustration of the interlayer Josephson coupling is strongest at $x = 1/8$. As a consequence, 3D bulk superconductivity does not easily occur. When the Ba content x in LBCO is changed to slightly smaller or larger values than $1/8$, the stripe order and hence PDW order gets weaker. As a consequence, the 3D-SC or uniform d -SC order rapidly develops due to weakening of the frustration of interlayer Josephson coupling. The onset of the 3D-SC, $T_{\text{c}}^{3\text{D}}$, shows a steep and deep dip at $x = 1/8$, forming two T_{c} -domes. Thus, it is likely that 3D SC in $x = 1/8$ LBCO below $T_{\text{c}}^{3\text{D}} \sim 5$ K develops due to inhomogeneity in the local hole density, resulting from Josephson coupling between dilute patches in the neighboring layers where the hole density deviates from $p = 1/8$.

The presence of fluctuating charge stripe has been confirmed for the La214 cuprate family (Miao et al., 2017). In LBCO with $x = 1/8$, static stripe order is absent above $T_{\text{CO}} = 55$ K ($= T_{\text{LTT}}$), instead the charge-stripe fluctuations with dynamic stripe correlations are observed by RIXS at temperatures above 55 K. They show up in RIXS as a broad peak centered near Q_{CO} via the x-ray resonant scattering process. This high- T scattering is found to comprise spectral weight by about 7 times larger than that of the low- T scattering from static charge stripes, similar to the relation between the precursory CDW and the quasistatic CDW in the YBCO family.

Regardless of the stripe order in La214 and the CDW in other cuprates, they show up as dynamic CDW correlations almost ubiquitously observed at high temperatures. At low temperatures, Q_{CO} (or Q_{CDW}) in La214 would be determined by coupling between CDW and SDW that organizes well-correlated stripe order. On the other hand, in other cuprates this mechanism does not work due to the presence of a spin gap and the absence of the LTT lattice structure. In this case, other material-specific details may be relevant for determining the characteristics of the quasi-static CDW.

The PG temperature T^* is not clearly defined in the stripe ordered cuprates, but a gap distinct from the d -SC gap opens near antinodes below $T_{\text{SO}} (= T_{\text{c}}^{2\text{D}})$ (He et al., 2009). Its momentum dependence is almost the same as that for underdoped Bi2212 below T_{pair} where PG and d -SC coexist. Also, in common with the canonical PG state is that SDW, CDW and pairing orders and their precursors are intertwined. From these, the stripe ordered state may be regarded as a PG state with a different appearance, and the onset of precursory SC at T_{pair} in the generic phase diagram would correspond to the onset of 2D superconductivity within a

CuO₂ plane without interlayer phase coherence. In fact, with lowering T below T_{pair} a BKT-like transition is observed in strongly anisotropic Bi2212 at T slightly above T_c , preempting the onset of 3D superconductivity (Corson et al., 1999; Li et al., 2005).

The generic phase diagram suggests that short-range and possibly fluctuating charge, spin, and pairing orders might be intertwined in the PG regime. The 2D superconductivity in the stripe ordered cuprates is best explained by the presence of PDW, a typical spin-charge-pair intertwined order. Also for non-La214 cuprates, a series of the STS experiments on Bi2212 have yielded evidences for PDW with spatially modulated superfluid density and superconducting gap magnitude that coexist with the uniform d -wave SC order below T_c (Hamidian et al., 2016; Edkins et al., 2019; Du et al., 2020) and persists to the PG regime above T_c . PDW appears in common with all the cuprate families and hence another candidate for the origin of PG.

Overdoped regime

This regime is roughly divided into two regions at around the higher end p_2 of the T_c dome, although p_2 is not a sharp boundary and dependent on homogeneity of doped hole density in real materials. One region is lightly overdoped region covering from the doping optimal for SC (p_{opt}) or a putative end of PG (p^*) to p_2 (see Fig. 3). T_c starts to gradually decrease and then is rapidly diminished toward p_2 . It appears that a Fermi liquid begins to be established with a well-developed large Fermi surface consistent in detail with the prediction of one electron band theory. This is supported by ARPES measurements where now relatively sharp peaks are observed even in the vicinity of the antinodes. In this “lightly overdoped region” CDW and other orders are not seen, but SC apparently survives maintaining fairly high T_c . The T^2 component in the in-plane resistivity in the normal state, characteristic of a Fermi liquid, gradually dominates. However, the T -linear component remains, which is characteristic of the resistivity above T^* in the PG regime and is interpreted as a sign of ‘strange’ metallicity.

Inelastic neutron scattering (INS) data indicate a dramatic suppression of magnetic spectral weight near the antiferromagnetic wavevectors $\mathbf{Q}_{\text{AF}} = (0.5, 0.5)$ (Wakimoto et al., 2007), which may be interpreted as a disappearance of the spin-fluctuation pairing glue, explaining why T_c goes down. Curiously the superfluid density $\rho_s(0)$ at $T \sim 0$ also starts to decrease for p beyond p_{opt} or p^* , although the normal-state carrier density continues to increase (Uemura et al., 1993; Bernhard et al., 2001; Bozovic et al., 2016). This is quite anomalous, since, in a clean conventional superconductor, all carriers are expected to form the SC condensate.

A typical interpretation of the reduction in $\rho_s(0)$ is a dominance of pair breaking due to disorder (high density of dopant atoms) coupled with a diminished pairing amplitude Δ_0 in the overdoped regime (Lee-Hone et al., 2017). Another is based on existence of two fluids in this region; one fluid involves incoherent quasiparticles (QPs), possibly related to SC condensate, and the other does coherent QPs originating from a non-SC Fermi liquid. In a real-space picture, the origin of the decreased superfluid density is a phase separation. With increasing p toward p_2 , non-SC phase, probably the genuine FL phase well beyond p_2 is gradually mixed up with the SC phase due to a significant distribution of local hole density p . If this lightly overdoped region were not a single phase but spatially phase separated, then a single-phase uniform d -SC state might be unstable in the cuprates. It is also possible to speculate a momentum-space “phase separation”. In this doping region, QPs are coherent on a large portion of the Fermi surface, contributing to the charge transport, but there remain incoherent QPs on some small portion which is responsible for the T -linear component in the resistivity and form superfluid below T_c .

For further overdoping ($p > p_2 \sim 0.25$) in the “heavily overdoped region”, SC is completely suppressed, and quasiparticles are coherent throughout the large FS, which is confirmed by both ARPES and quantum oscillations measurements. Most of the properties in this region are normal except for that the spin wave, characteristic of localized spins, is robustly present without changing its dispersion in the AF ordered phase. While spin fluctuations at $\mathbf{Q}_{\text{AF}}$ fade out, pronounced spin fluctuations remain at smaller wavevectors (Dean et al., 2013), implying that strong electron correlations persist even in heavily overdoped cuprates. Then, it is speculated that a second high- T_c dome may appear in the doping region (e.g., $p > 0.4$) next to the heavily overdoped FL (Maier et al., 2019). This region is not accessible for the representative cuprate families such as LSCO, YBCO, Bi2212, and even overdoped Tl2201. At present, at least two cuprate materials, $\text{Cu}_{0.75}\text{Mo}_{0.25}\text{Sr}_2\text{YCu}_2\text{O}_{7.54}$ and $\text{Ba}_2\text{CuO}_{4-\gamma}$ synthesized under high pressures, show SC with $T_c \sim 80$ K and are supposed to have doped hole density in the range between 0.4 and 0.5.

Strange metal regime

The metallic state in the high T region above the PG T^* and that in the region from the putative critical doping p^* to near the end of the T_c dome are recognized as “bad” metal and “strange” metal, respectively. In the high-temperature “bad” metal regime, the in-plane resistivity continues to increase linearly with T without a tendency for saturation, while in the low-temperature “strange” metal regime the T -linear resistivity persists even toward $T = 0$ (Martin et al., 1990; Cooper et al., 2009) when superconductivity is suppressed by strong magnetic fields or by disorder (see Fig. 6). These two are in principle distinct - a system can be bad without being strange and vice versa. However, the cuprates are apparently both bad and strange. In a range of doping, near p_{opt} , the resistivity is linear in T all the way from $T \sim 0$ (when SC is suppressed) up to the highest temperatures as measured (typically ~ 1000 K) (Gurvitch and Fiory, 1987). The slope of the T -linear resistivity is constant, showing no discernible crossover from “strange” to “bad” metal regime. Given that both are not distinguished in the cuprates, the high-temperature “bad metal” regime above T^* is labeled by “strange metal” in the phase diagram (Fig. 3).

The basic difference of the high- T strange metal from a conventional metal is the absence of quasiparticles. In a normal metal, the resistivity saturates at high temperatures when the mean free path (l) of charge carrier becomes of the order of its de Broglie wavelength λ_F ($\lambda_F = 2\pi/k_F$ where k_F is the Fermi wavenumber) – the Mott-Ioffe-Regel (MIR) limit. Since the magnitude of the

Fig. 6 Typical temperature dependent in-plane resistivity measured for $\text{La}_{2-x}\text{Sr}_x\text{CuO}_4$ with $x = 0.20$. The resistivity values measured under constant pressure are transformed to the values at constant sample volume (isochoric) using the data of the pressure dependence of resistivity and bulk modulus. The resistivity increases linearly to the highest temperatures without showing saturation at temperatures well exceeding the Mott-Ioffe-Regel limit (shaded region; its numerical value is somewhat arbitrary). The T -linear resistivity persists even toward $T = 0$ (red dashed line) when the superconducting transition is suppressed by magnetic fields.

cuprate resistivity in the high- T region is larger than that of typical metals by more than an order, the resistivity well exceeds the MIR limit in the high T region (Hussey et al., 2004). Nevertheless, the resistivity shows a “metallic” linear-in- T dependence. Therefore, well-defined quasiparticles do not exist and hence the resistivity is difficult to be interpreted in terms of propagating quasiparticles in the Boltzmann transport theory. The failure of the ordinary physics of good metals has provided strong motivation for proposing quite an exotic theory such as holographic duality (Zaanen, 2019). The origin of this behavior is, however, still a subject of much debate, but is of obvious importance since PG and/or FL appear to get born upon cooling from this regime, perhaps one of the most mysterious aspects of cuprates. PG and FL emerge from totally incoherent ‘strange metal’ by partial restoration of quasiparticle coherence over a range of the Fermi surface (Fermi arc) in the former and a complete restoration in the latter.

In the low- T strange metal regime, the T -linear resistivity persistent down to $T \sim 0$ indicates a scale invariance or a vanishing intrinsic energy scale which is characteristic of quantum critical metals. When subjected to infrared photons with frequency ω , the low-energy optical conductivity of scale invariant metals is set by the larger energy scale between $k_B T$ and $\hbar\omega$, that is, the inelastic scattering rate of electrons, $\hbar/\tau \sim \max[k_B T, \hbar\omega]$ (van der Marel et al., 2003). In the same way, under external magnetic fields B , the magnetoresistance, $\Delta\rho/\rho_0 = [\rho(B) - \rho(0)]/\rho(0)$, is controlled by $\hbar/\tau \sim \max[k_B T, \mu_B B]$, μ_B being the Bohr magneton. A crossover in magnetoresistance is actually observed at low temperatures from $\Delta\rho/\rho_0 \sim B^2$ at low fields to $\Delta\rho/\rho_0 \sim B$ at high fields (Ayres et al., 2021).

The recent experimental findings challenge the view of the scale invariance in association with QCP. First, experimental effort to unambiguously identify the presence of the QCP is limited by the onset of SC at fairly high temperature. Second, the T -linear resistivity extending to $T \sim 0$ persists over a broad doping range, from p_{opt} to around the end of the T_c dome in contrast to the above QCP scenario. Third, concerning the quantum critical wedge in the higher doping side, $p > p^*$, a big question that remains unanswered is how really different the supposed Fermi liquid at lower temperatures is from the strange metal at higher temperatures. ARPES shows there is only a weak crossover line that separates these two regimes, but other experimental probes fail to identify it.

Conclusion

Summary

Recent progress in various advanced spectroscopies has revealed that the T - p phase diagram of hole-doped cuprates is much more complicated than the widely spread ‘standard’ phase diagram (Fig. 2). The generic phase diagram incorporates various spin, charge and electron-pair orders in addition to the unconventional d -wave SC order. It turns out that various ordering phenomena including their precursory orders predominantly take place in the PG regime. Thus, the PG regime seems a home to these orders. The PG regime appears to also accommodate some intra-unit-cell ($q = 0$) orders such as circulating orbital current order and nematic order, which are observed exactly below the pseudogap temperature T^* , but they cannot create a gap by themselves. These recent findings pose additional questions, which are primary orders and how they are inter-related (or intertwined) to shape the generic phase

diagram and finally to establish superconductivity at T_c of ~ 100 K with global phase coherence. To this, the spin-charge stripe order realized in the La-based cuprates is an instructive example. The stripe order displays how the spin and charge orders are intertwined with the pairing correlation to form a spatially modulated SC order, PDW, and thereby 2D superconductivity.

The high-temperature metallic state above T^* is recognized as a strange or bad metal regime which cannot be described by the quasiparticle picture. The quasiparticles are totally absent or completely incoherent, but nonetheless the T -linear resistivity persists up to the highest temperature measured. The origin of this behavior is still a subject of much debate, but the understanding of this regime is of obvious importance since PG in the underdoped region and probably FL in the heavily overdoped region appear to get born upon cooling from this regime. The failure of the ordinary physics of good metals has provided strong motivation for proposing quite a exotic theory such as holographic duality.

Another important observation by the advanced spectroscopy is the persistence of spin and charge excitations with SDW (or AF) and CDW correlations up to temperatures even higher than T^* and in the entire SC doping region. Both cover a wide momentum region centered at AF and CDW wavevectors and extend to very high energies of order of a few tens of eV. They are not only possible sources of strong electron scattering that makes the electrons completely incoherent but also possible glues for the formation of Cooper pairs. The AF spin fluctuations have been widely believed as a strong candidate of the pairing glue. A question to be answered is whether the CDW fluctuations play a role of an independent or additional glue to enhance the SC T_c or conversely as a pair breaker for d -SC.

Outlook

Magnetic phase diagram

Since the various orders emerge with doping into the Mott insulating phase, the cuprate phase diagram has been investigated mainly in the temperature-doping plane. In order to better understand the known phases and to search for hidden phases, it would be helpful to explore a phase diagram using a control parameter other than doping. Pressure and magnetic field are typical control parameters for other systems. While pressure, either uniaxial or hydrostatic, is not an effective perturbation to change the completion and/or intertwining among different phases in cuprates, intense magnetic field (B) has recently been found to substantially affect the SC state as well as the competition between SC and CDW orders (Yu et al., 2016).

The B - T phase diagram of cuprates with B in the direction perpendicular to the CuO_2 planes, has not been fully investigated because of the limitation of available magnetic field strength, and continues to be a matter of debate. One of the unsettled problems is that experiments so far made have never observed the upper critical field H_{c2} , i.e. the pair-breaking field, convincingly even near T_c . The vortex lattice in cuprates easily melt at a field value $H_m(T)$ much weaker than the inferred $H_{c2}(T)$, and the vortex liquid state is found to persist above T_c up to T_{pair} (Li et al., 2013). As a consequence, the vortex liquid phase occupies a surprisingly large region of the B - T phase diagram. Extending to a temperature T_{pair} and to an experimentally inaccessible high field. Further, the spatially modulated SC state (PDW), a spin-charge-pairing intertwined order typically observed in the stripe order, appears to be stabilized in the region of a vortex halo as evidenced by the STS measurement on Bi2212 (Edkins et al., 2019). However, effects of magnetic field on CDW and SDW orders that probably coexist with the vortex liquid state remain open. Perhaps related open question is whether or not an electron Fermi surface pocket, which is supposed to emerge as a consequence of Fermi-surface-reconstruction in the presence of a static CDW, exists in the vortex liquid region suggested by the observation of quantum oscillations (Doiron-Leyraud et al., 2007).

New spectroscopy and hidden orders

Unraveling the origin of the pseudogap (PG) state of the high- T_c cuprates has been an issue of continuous challenge for almost three decades. PG turns out to be a playground of several orders. Among them, SDW order, superconducting order and CDW order are now well known and experimentally confirmed. These three orders and their precursors are found to exist in the PG regime. Nevertheless, it remains unclear how they form the PG state above T_c . This suggests that there might be a hidden order which has not been detected by the currently available experimental probes, and would be a remaining piece for finally resolving the PG puzzle.

To uncover hidden orders, a challenge for developing a new spectroscopy may be needed, such as one, for example, that allows for a detection of dipole-forbidden optical excitations or is sensitive to various forms of vortices or topological defects as well as to orders and excitations involving orbital degree of freedom. In the history of the research of high- T_c superconductivity, breakthroughs have always been made by new spectroscopy.

Abstract

Superconductivity, which was previously believed to occur only at low temperatures close to zero Kelvin, has recently been believed to occur even at room temperature. Experimental results of superconductivity at high temperatures close to room temperature have been reported in hydrogen-based materials, hydrides, although ultrahigh pressures in excess of 100 GPa are required.

Key points

- Explore the occurrence of superconductivity at higher temperatures, including room temperature.
- Experimental results of hydrogen-based superconductivity.
- Requirement of very high pressures for hydrogen-based high-temperature superconductivity.

Introduction

Superconductivity, which was previously believed to occur only at low temperatures close to zero Kelvin, has recently been believed to occur even at room temperature. Although it requires extreme pressure conditions of over 1 million atmospheres (about 100 GPa), the RTS (room-temperature superconductivity) is not a dream but has become a concrete possibility, raising hopes for the emergence of superconducting materials without cooling in the near future. For over a century since the discovery of the superconductivity in the early 20th century, researchers have focused on increasing the critical temperature (T_c) for reducing the cooling costs. The historical progression is illustrated in Fig. 1. Following the rapid rise in the T_c observed in the 1980s with the discovery of copper oxide superconductors, the recent surge in research on hydride superconductors (hydrogen-based superconductor) has sparked considerable interest. How did this rapid development occurred?

Theoretical predictions

It is generally not easy and challenging to theoretically predict the crystal structure and resulting properties of a material under high pressure, which greatly influences its characteristics. However, recent advancements in computational methods have significantly improved the accuracy of prediction of stable structures under pressure. The discovery of superconductivity in hydrogen sulfide (Drozdov et al., 2015) was initiated by theoretical predictions (Li et al., 2014) and later confirmed through experiments, which revealed that the observed crystal structure and T_c (Einaga et al., 2016) were consistent with the theoretical predictions (Duan et al., 2014). This not only proves the accuracy of the theoretical prediction, but also that this superconductivity is based on the BCS theory. The success of this theoretical prediction led to the search for the next hydride superconductor, and calculations were actively carried out. One element was selected from the periodic table to be combined with hydrogen, and the ratio of hydrogen, pressure, and structure at which the hydride would be stable were calculated. They then use these structural parameters to calculate the superconducting properties, proposing various hydrogen-rich compounds as potential candidates for high-temperature superconductivity. In other words, hydride synthesis experiments are being conducted in the computer before actual experiments in laboratory. Table 1 lists some of the candidates that have the potential to realize room temperature superconductivity (Wang et al., 2012; Feng et al., 2015; Liu et al., 2018).

Synthesis of superconducting hydrides

Pressure generation and measurement technique

Before discussing the specific details of hydride superconductors, the generation of high-pressure environments exceeding 100 GPa and the techniques for measuring superconductivity within these environments are briefly introduced in Fig. 2. See references (Shimizu et al., 2005) for details. High pressure is generated by a Diamond-Anvil Cell (DAC). A photograph of the DAC for low-temperature use is shown in Fig. 2C, and its pressure generation section is shown in Fig. 2B. The DAC is composed of two diamond anvils. The sample and pressure transmitting medium are enclosed in a space between two diamond anvils. Four electrodes are usually placed on the sample to perform a four-terminal electrical resistance measurement. These electrodes can also be deposited on the surface of the upper diamond anvil. External heating of the sample can apply to the sample by irradiating with infrared lasers.

Table 1 Candidate hydrides with potential for room temperature superconductivity.

Hydrides	$T_c(K)$	P (GPa)
MgH ₆	260	300
CaH ₆	220–235	150
YH ₆	251–264	120
YH ₁₀	305–326	120
LaH ₁₀	274	200

The electrical resistance of the sample is measured by four electrodes. (B) schematic drawing of the assembly of the sample and electrodes between diamond anvils. (C) photograph of DAC.

Synthesis through molecular dissociation

Hydrogen sulfide (H_2S) is a gas molecule at ambient temperature and pressure. Its boiling point is approximately 200 K, and it can be liquefied by introducing H_2S gas into a DAC that has been cooled below its boiling point using a refrigerator. Thus, in the case of H_2S , the sample and pressure medium in Fig. 2A are combined and equal to sample. Upon pressurization, H_2S liquid immediately solidifies, and further pressurization leads to the metallization, then the superconductor with a T_c of 200 K is achieved (Drozdov et al., 2015).

Reproduction experiments and structural analysis using synchrotron X-rays (SPRING-8) have revealed that hydride (H_3S : sulfur hydride SH_3), whose hydrogen content is higher than that of hydrogen sulfide (H_2S), is the true entity of the 200 K superconductor. Furthermore, X-ray structural analysis revealed that sulfur is precipitated during the synthesis process, and as shown in Eq. (1), H_3S with a higher hydrogen content is formed from parent substance, H_2S displacing sulfur under high pressure as Fig. 3.

This is an example of hydride synthesis through the molecular dissociation. For the candidate substances listed in Table 1, there is currently no parent substance (such as H_2S for H_3S) at this moment.

Direct synthesis from element and hydrogen

After the discovery of the superconductivity of hydrogen sulfide (Drozdov et al., 2015), a direct synthesis of hydride from sulfur and hydrogen was attempted. By substituting sulfur for the sample and hydrogen for the pressure medium in Fig. 2, this synthesis was performed. After pressurization up to 150 GPa, sulfur transformed to metal, but any reaction with hydrogen did not occur. When the metallic sulfur was heated by an infrared laser, the hydrogen in contact with the sulfur was heated together and the synthesis reaction ($2\text{S} + 3\text{H}_2 \rightarrow 2\text{H}_3\text{S}$) occurred. This was monitored by the powder X-ray diffraction analysis, which was performed simultaneously with this laser heating and electrical resistivity measurements. When the DAC was cooled afterwards, the superconducting transition was observed at about 200 K, as in Drozdov et al., 2015 reported. In comparison to the synthesis through the molecular dissociation mentioned, this direct synthesis method was expected to have an advantage in purity and crystallinity of H_3S without the excess sulfur, but the observed T_c remained the same (Nakao et al., 2019).

This direct synthesis method served as a model for the syntheses of superconducting hydrides, and most of the later synthesis experiments employed this method.

Near room-temperature superconductivity in hydrides

Lanthanum hydride

Among the candidates listed in Table 1, the synthesis of lanthanum hydride (LaH_{10}) and its superconductivity with a transition temperature exceeding 250 K were reported nearly simultaneously by research groups from the United States and Germany in 2019. In both cases, the superconductivity was discovered at pressures and temperatures that were approximately equal to the values shown in Table 1 (Somayazulu et al., 2019; Drozdov et al., 2019). LaH_{10} has a structure in which hydrogen atoms surround lanthanum atoms in a cage-like arrangement as shown in Fig. 3; although the position of the hydrogen element cannot be determined by X-ray structure analysis, the structure formed by lanthanum is consistent with what theoretical calculations predict. The synthesis methods of both groups are based on Fig. 2A, with the German group (Drozdov et al., 2019) using hydrogen and the

Fig. 3 Typical crystal structures of superconducting hydrides. (left) H_3S . Hydrogen atoms are arranged in a straight line between the lattices of sulfur atoms. (right) LaH_{10} . Hydrogen atoms surround lanthanum atoms.

US group (Somayazulu et al., 2019) using ammonia borane (NH_3BH_3) as a hydrogen source. After pressurizing the sample at room temperature to the theoretically predicted pressure, the sample was heated by an infrared laser and synthesized by reacting the sample with hydrogen in contact with the sample or with hydrogen generated from ammonia borane. The use of ammonia borane as a hydrogen source has become more common in recent years due to the convenience of experimental setup compared to using hydrogen directly.

USOs (unidentified superconducting objects)

Many hydride superconductors have been predicted from theoretical calculations and many demonstration experiments have been reported. It is foreseen that the day when the superconducting transition temperature exceeds room temperature is approaching. In this context, in 2020, a report emerged of observing the superconductivity with the T_c exceeding room temperature at 250 GPa in a carbon-sulfur hydride compound (CSH) (Snider et al., 2020). Furthermore, in 2023, the observation of room-temperature superconductivity in nitrogen-doped Lu hydride (NLuH) at very low pressure, ~ 1 GPa was announced (Dasenbrock-Gammon et al., 2023). There on the Web and in newspapers are claiming “room-temperature superconductivity has finally been achieved.” However, at the time of writing this article, no research group has been able to reproduce these experiments, and the paper (Snider et al., 2020) has been retracted.

These things remind us the term of “Unidentified Superconducting Object” (USO) that defined by Prof. Kitazawa to refer to materials that failed to satisfy all of the following conditions during the fever of copper oxide superconductors in the 1980s: (1) observation of zero resistance, (2) observation of the Meissner effect, (3) determination of crystal structure, and (4) reproduction by other research groups. At the moment, (3) and (4) are missing from both CSH and NLuH, so a follow-up report will be forthcoming.

Future prospects

Toward higher temperatures

How can we achieve higher transition temperatures (T_c)? One approach is to substitute or add lighter elements as constituents. In the case of hydrogen sulfide, this would involve replacing sulfur with a lighter element in the same group, such as oxygen, or adding oxygen to the system. Such proposals based on theoretical calculations have been put forward, including the suggestion of adding phosphorus (Ge et al., 2016; Nakanishi et al., 2018). These substitutions and additions have been common strategies employed whenever a new superconductor is discovered. However, as of now, no significant increase in T_c has been observed through these methods in superconducting hydrides.

Toward lower pressure

Theoretical calculations and experiments are underway for ternary hydrides with one more parent element. The purpose of this research is to explore superconducting hydrides that can be synthesized at lower pressures, in addition to achieving higher transition temperatures (T_c). The ultimate goal is to synthesize room-temperature, ambient-pressure superconductors that do not require pressure. If the synthesis pressure can be reduced to less than 50 GPa, which can be generated by a high-pressure apparatus such as a KAWAI-type press, it will make possible to synthesize the superconductors with millimeter-sized samples. Further reduction of the pressure to a few GPa could enable the synthesis of centimeter-sized samples. This would enable the neutron diffraction experiments with sufficient intensity and reveal the nature of hydrogen, the key element in hydride superconductors. Then this would contribute to a better understanding of hydride superconductors and the development of pressure-free room-temperature superconductors will become more realistic.

Control of hydrogenation

There have been several theoretical proposals for hydrides exceeding room temperature, but experimental verification has been challenging. This is partly due to the high cost of experiments consuming diamonds, but also because successful examples that match the theoretical predictions are limited. For example, different hydrides with different amounts of hydrogen are synthesized. During the synthesis process, it is possible that more stable hydrides with a different hydrogen content exist along the temperature-pressure path, which prevents further hydrogenation. There may be an optimal temperature and pressure pathway that avoids this problem, but it is considered difficult to clarify the synthesis pathway by theoretical calculation due to the large amount of calculation.

There is no doubt that hydrogen-rich compounds are strong candidates to realize room-temperature superconductivity. Many candidate materials will be theoretically proposed, experimentally tested, and valuable results will be fed back to theory. This will lead to a more precise selection of candidate materials.

Conclusion

Although an extreme environment of ultrahigh pressure is necessary, hydrogen has been growing expectations not only as an energy source but also as a source of superconductor to conserve energy. However, it is expected to take some more time before we can fully utilize this near room-temperature superconductivity. Current efforts focus on reducing the required pressure and on considering utilizing them even at high pressures. Hydrides are a strong candidate for room-temperature superconductivity, and at the same time, a significant exercise in materials science.

Unconventional superconductivity

Igor I Mazin, Department of Physics & Astronomy, George Mason University, Fairfax, VA, United States

© 2024 Elsevier Ltd. All rights reserved.

Abstract

The division of the broad field of superconductivity into *conventional* and *unconventional* is conditional, just as any binary division based on a subjective notion of “conventionality”. It is often in the eye of the beholder. Still, it is often a useful, even if fuzzy, line between superconductivity that follows, with modifications, the traditional framework established by Bardeen, Cooper, Schrieffer, and Eliashberg, and that which deviates from that path.

Key points

- Defining unconventional superconductivity
- Higher angular momenta
- Examples of unconventional superconductors
- Odd-frequency order parameter
- Conditions conducive for unconventional superconductivity
- Some useful theorems
- Multigap superconductors
- Further reading

Unconventional superconductivity is an umbrella term that has been used by different researchers with different meaning. Common definitions refer to conventionality in three separate aspects: pairing mechanism, pairing symmetry, and transition temperature. In addition, occasionally conventional in their mechanism superconductors are considered unconventional because of their specific unusual properties. Examples of that include, for instance, Ising superconductors and topological superconductivity.

The most restrictive definition of conventional superconductors (CSC) stipulates that CSC are (a) mostly mediated by adiabatic (e.g., respecting the Migdal theorem) harmonic phonons, (b) have isotropic or nearly-isotropic s-wave order parameter and (c) have critical temperature below 20–30 K. Such a limiting definition is rarely called for. Recently discovered superconducting superhydrates are believed to be phonon-mediated and isotropic s-wave, despite having critical temperatures approaching the room temperature and possibly nonadiabatic and anharmonic phonons, yet they are usually classified as CSC. In fact, these criteria are not independent. Indeed, a purely attractive interaction, such as phonon-mediated, cannot generate a superconducting state with a sign-changing order parameter, and, conversely, a pure repulsive (in the momentum space) interaction cannot generate a state that has an order parameter of the same sign everywhere.

Most scientists agree that a pairing state that involves an order parameter of lower point group symmetry than the hosting crystal (p-wave, d-wave etc.) should be classified as unconventional, regardless of the transition temperature. Obviously, such states cannot originate from pure phonon attraction, so pairing interaction is by definition unconventional in that sense. On the other hand, repulsive interactions, such as those of magnetic origin, may result in a sign-changing order parameter of the s-wave angular symmetry. Such states are often called $s_{\pm}$, and also usually classified as unconventional.

At the dawn of superconductivity it was believed that unconventional superconductors are but a theoretical Kunststück that is not supposed to occur in real materials, for the reason that nonmagnetic impurities are pair-breaking for such a state, and—as it was thought—would kill such superconductivity dead except in exceptionally clean samples.

It turned out that reality is not that bleak, and, in particular, that unconventional superconductors tend to have short coherence lengths, and therefore less prone to pair breaking (which is controlled by the ratio of the coherence length and the mean free path). In the moment, a number of well-studied superconductors have been convincingly demonstrated to have unconventional pairing symmetries. This includes high- T_c cuprates (d-wave), Fe-based superconductors ($s_{\pm}$); a number of heavy fermion systems, where the exact symmetry of the order parameter has not been established above reasonable doubt, are generally believed to host unconventional, possibly triplet, superconductivity. Same can be said about many organic (quasi-1D) superconductors. An interesting case is Sr_2RuO_4 : For at least 20 years it was believed it was a triplet p-wave superconductors, but recent experiments convincingly point toward a singlet state. Yet, there is little doubt that superconductivity there, while still unresolved, is unconventional.

A separate, even more exotic case is the so-called odd-frequency superconductivity, whereby the frequency-dependent order parameter is assumed to change sign not (or not only) in the momentum space, but when the frequency argument changes its sign. No realistic candidates among real materials have been identified, albeit there were some proposals of this character, but there is some experimental evidence that such states can be generated by proximity effects near superconductor-ferromagnet interfaces.

The number of unconventional superconductivity candidates identified in the last decades is considerable, and suggests several empirical rules that are conducive for UCSC. These tend to be low-dimensional (quasi-1D or quasi- 2D), and tend to have a phase diagram where superconductivity emerges near magnetic (usually antiferromagnetic) states. This is not unexpected, given that UCSC is likely to be mediated by some kind of spin fluctuations, and both proximity to magnetism and low dimensionality favor spin fluctuations.

Let us now discuss in more details the principal classes of UCSC.

High- T_c cuprates emerge in the vicinity of the Mott-Hubbard metal insulator transition. The Cu^{2+} ions have one hole in the rather localized d -shell, which is therefore subject to strong local Coulomb repulsion, $U \gg t$, where t is the one-electron hopping parameters for d -electrons. This generates a nearest neighbor antiferromagnetic superexchange, proportional to t^2/U . In parent compounds this results in a checkerboard antiferromagnetic ordering with the wave vector $\mathbf{Q} = (1,1,0) \pi/a$. Upon doping the magnetic order melts and the insulating state is being transformed into a strongly correlated metal. Instead of the static order, Cu spins now fluctuate with the same wave vector $\mathbf{Q}$.

The one-electron band structure of these cuprates is formed by a single x^2-y^2 orbital, so the corresponding Fermi surface is close to a circular cylinder. It is easy to see that if one postulates the d -wave order parameter with the same symmetry, x^2-y^2 , spin fluctuations with the wave vector $\mathbf{Q}$ will be spanning two parts of the Fermi surface with the opposite signs of the order parameter and therefore be pairing. This simple argument has led to the view, shared by a majority of researchers, that superconductivity in cuprates is driven by spin-fluctuations.

Similarly, in Fe-based superconductors, the magnetic order in the parent antiferromagnets corresponds to $\mathbf{Q} = (1,0,0)\pi/a$ in the single-Fe unit cell, and the Fermi surface, in most cases, consists of two groups, one centered around $\mathbf{q} = (0,0,0)\pi/a$ and the other around $\mathbf{q} = (1,0,0)\pi/a$; so assigning different signs to the order parameters in the two sets assures that spin-fluctuations are pairing. Thus, a plurality, and may be even majority of scientists believe these materials, as well, to be fluctuations-driven.

These two example are, arguably, the best studied UCSC. Yet, there is a solid body of evidence in favor of unconventional pairing in numerous other materials, including, but not limited to organic metals, heavy fermions, or twisted bilayer graphene.

Some useful theorems regarding unconventional pairing symmetries are: (1) A fully local (*i.e.*, contact) Coulomb repulsion, such as the Hubbard interaction, cancels out if the order parameter integrates to zero over the entire Fermi surface (regardless of the nature of the pairing interaction). This can be also reformulated by applying the Fourier transform and considering the structure of a Cooper pair in coordinate space. In this case, the component of the pair are localized on different lattice sites. In case of cuprates (d -wave) these are nearest neighbors in the square lattice, and in case of Fe-based superconductors ($s_{\pm}$) on the second neighbors. (2) While the order parameters itself may follow a lower-symmetry representation than the full crystal symmetry (A_{1g}), its amplitude, *i.e.*, the excitation gap, usually does follow the full symmetry (some exceptions to this rule, often called “nematic” superconductivity, have been proposed theoretically). (3) Even if the order parameter does not obey the point group, it is, including the phase, subject to the Bloch theorem, so that $\Delta(\mathbf{k}) = \Delta(\mathbf{k} + \mathbf{G})$, where $\mathbf{G}$ is a reciprocal lattice vector. It is a powerful theorem because it forces order parameter nodes at some special high-symmetry points.

Finally, it is worth bringing up yet another class of materials, multigap superconductors, where the magnitude of the order parameter changes exceptionally strongly over the Fermi surface or between different Fermi surface pockets. These are not usually called UCSC now, but they were not appreciated (albeit theoretically discussed already in the late 50s) until the discovery of a two-gap superconductivity in MgB_2 in 2001—at that time MgB_2 was routinely referred to as an unconventional, but phonon-driven superconductor.

Abstract

In Bardeen, Cooper and Schrieffer's (BCS) theory of superconductivity, the usual metallic parabolic nearly-free-electron band is modified by opening a gap at the Fermi level. The electronic density of states is zero within the gap and presents peaks at the gap edges. Many materials have superconducting properties that deviate from BCS theory and, as a consequence, the density of states is very different, too. The differently shaped density of states signals new paradigms in superconductivity, such as two-band, anisotropic, or multigap superconductivity. Here, measurements of the density of states obtained using Scanning tunneling microscopy (STM) in representative compounds are reviewed and future prospects of advances in superconductivity using STM are discussed.

Key points

- Present basic aspects of the superconducting density of states.
- Discuss the tunneling conductance in representative examples.
- Discuss methods to address new superconductors.

Introduction

The superconducting state is characterized by the condensation of pairs of electrons into Cooper pairs described by a macroscopic quantum wave function $\Psi(\mathbf{r})$ which has a smooth dependence on the position $\mathbf{r}$ (Leggett, 2005; Larkin, 2005). Consequences are the establishment of dissipationless transport and of flux quantization (Kirtley and Tsuei, 2005; Brandt, 2005), both of great importance for applications (Bishop, 2005a; Gurevich, 2005). The occurrence of superconductivity is described by Bardeen, Cooper and Schrieffer's (BCS) theory (Bennemann, 2005, 2023). BCS theory describes the condensate as well as its excitations. The latter are located at an energy E above the superconducting gap Δ . Within BCS theory, the pairing interaction energy is of the order of the Debye temperature and much larger than the superconducting gap Δ , both also much smaller than the Fermi energy E_F .

After more than 66 years of BCS theory, numerous compounds and systems have been shown to be superconducting, with critical temperatures ranging from below a mK up to near room temperature (Bishop, 2005b; Qin and Dou, 2005). The pairing

interaction energy and Fermi temperatures vary across many orders of magnitude, too (Nozières and Schmitt-Rink, 1985; Fazio and van der Zant, 2001; Shibauchi et al., 2020; Blatter et al., 1994). The energy dependence of the excitations of the superconducting state depends on the pairing interaction and on the coexistence with other magnetic or charge ordering phenomena. As a consequence, the electronic excitations can be very different in different superconducting materials.

In Fig. 1A, the energy dispersion relation within BCS theory is schematically shown. The superconducting density of states is obtained by integrating over the wavevector (Fig. 1B). In BCS theory, superconductivity modifies the free electron parabolic electronic energy dispersion relation and opens a gap with size $\pm\Delta$ above and below the Fermi level. This provides sharp peaks in the density of states at the superconducting gap energy $\pm\Delta$ and no states for $|E| < \Delta$ (Fig. 1B).

The superconducting density of states can be probed by many measurements, such as specific heat, thermal conductivity, nuclear magnetic resonance, and penetration depth. All these probes address however the energy integral of the density of states. To obtain the energy dependence of the density of states, one has to measure directly the electronic band structure. This requires injecting or retrieving electronic excitations from the superconductor, which can be done by tunneling or by photoemission (Cleland, 2005; Margaritondo, 2005). Tunneling conductance experiments can be usually made at lower temperatures than photoemission. Furthermore, a magnetic field can be applied. Thus, tunneling conductance measurements have been more widely applied to superconductors.

Tunneling conductance can be measured between a superconductor and another electrode through an evaporated insulating barrier (Dragoman and Dragoman, 2005) or by approaching a tip to the surface of a superconductor and using vacuum as the tunneling barrier. Here the focus is on results obtained using the latter approach with a Scanning tunneling microscope (STM). Other aspects of superconductivity and tunneling, such as DC and AC Josephson effects, Andreev reflection or superconducting vortex physics are discussed by Cleland (2005), Fischer et al. (2007), Suderow et al. (2014), Tafuri (2023), and Mikitik (2023).

Overview

Tunneling conductance

Bringing two metallic electrodes at a sufficiently short distance, of the order of the nm, produces a tunneling current that flows between both electrodes. This is schematically shown in Fig. 2. The tunneling current is given by the overlap between the

Fig. 1 (A) The dispersion relation for free electrons is shown by the red dashed line. In a superconductor below T_c , the dispersion relation is modified by the opening of the superconducting gap, following BCS theory. The corresponding band structure is shown by the colored red and blue lines. Red is for electron-like excitations and blue is for hole-like excitations. (B) The BCS density of states as a function of the energy (blue line). (C)–(F) Schematic view of different gap structures is shown as blue lines within a two-dimensional Brillouin zone (black square). Dashed blue lines provide the Fermi wave vector. (C) S-wave BCS single gap. The gap magnitude (Δ) is constant over all the Fermi surface. (D) Two disk-shaped Fermi surfaces (grey circles) having two different magnitudes of the superconducting gap. (E) A square-shaped Fermi surface, with two different values of the superconducting gap along two directions. (F) Fermi surface of a band structure that crosses the Brillouin zone. The gap magnitude is different on the central pocket as compared to the pockets at the corners of the Brillouin zone.

Fig. 2 Schematic view of tunneling between tip and sample in an STM. The tunneling gap of width d is shown by the vertical arrow. The electronic wave functions (Ψ_T and Ψ_S for tip and sample) are schematically represented by the blue and red lines. The bias voltage is shown by a horizontal grey arrow. Work functions of each electrode are shown schematically as Φ_T and Φ_S for tip and sample, respectively.

wavefunctions extending into vacuum. Bardeen's formalism, modified by Tersoff and Hamann for STM (Bardeen, 1961; Tersoff and Hamann, 1983, 1985; Agrait et al., 2003), describes the tunneling current as

$$I(V) = \frac{4\pi e}{\hbar} \int_{-\infty}^{\infty} dE |M|^2 N_s(E - eV) N_t(E) (f(E - eV) - f(E)), \quad (1)$$

where e is the electron charge, $\hbar$ is the Planck's constant, E is the energy, V is the applied voltage, M is the tunneling matrix element, $N_s(E - eV)$ and $N_t(E)$ are the densities of states of tip and sample, and $f(E)$ is the Fermi function.

Here the focus is on the situation where a normal metal such as Au or Pt is used for the tip.¹ At energies approximately below ± 100 meV of the Fermi level, N_t is approximately flat and constant and can be taken out of Eq. (1). Then one can write for the bias voltage dependence of the tunneling conductance $\sigma(V) = \frac{dI}{dV}$.

$$\sigma(V) \propto \int_{-\infty}^{\infty} dE N_s(E) \frac{\partial f(E - eV)}{\partial V}. \quad (2)$$

At sufficiently low temperatures, $\frac{\partial f(E - eV)}{\partial V}$ is close to a δ function, for which one obtains that the tunneling conductance versus bias voltage V follows the superconducting density of states $\sigma(V) \simeq N_s(eV)$.

In a simple metal, with only a single band crossing the Fermi level and a fully spherical Fermi surface, BCS theory leads to an equally isotropic superconducting gap, schematically shown in Fig. 1C (in two dimensions for clarity). Then, Eq. (2) provides an excellent account of the tunneling conductance, which closely follows the BCS relation $\sigma(V) \simeq N_s(E = eV) \propto \frac{E}{\sqrt{E^2 - \Delta^2}}$.

Distribution of values of the superconducting gap

Most materials are however not simple metals and can have quite an intricate set of bands crossing the Fermi level. Let us consider a hypothetical metal with two isotropic bands crossing the Fermi level (Fig. 1D). To find the superconducting density of states, one has to integrate the reciprocal wave vector dependence. The result is a sum with two contributions $N(E) = N_{s,1}(E) + N_{s,2}(E)$, each $N_{s,i=1,2}(E)$ eventually following the BCS relation for a fully opened superconducting gap with generally different values Δ_1 and Δ_2 . Similarly, a superconductor with an anisotropic crystal lattice might have a single band crossing the Fermi level, but different values of the superconducting gap along different crystalline directions (Fig. 1E). Alternatively, there can be bands located at different places on the Brillouin zone, showing different values of the superconducting gap (Fig. 1F). The latter cases might again lead to $N(E) = N_{s,1}(E) + N_{s,2}(E)$ with different gap values $\Delta_{1,2}$. Generally there can be many contributions to $N(E)$ from portions of the band structure close to the Fermi level located in places in the Brillouin zone with very different values of the superconducting gap Δ_i .

¹When using a superconducting tip as Al, Pb, or Nb, $N_t(E - eV)$ is strongly featured in a similar energy range as the superconducting counter electrode. In that case, Eq. (1) has to be evaluated in full to understand the tunneling conductance (Rodrigo and Vieira, 2004; Rodrigo et al., 2004a; Proslir et al., 2006; Guillamon et al., 2008; Kohen et al., 2006; Liu et al., 2021a; Pan et al., 1998; Heinrich et al., 2018), with resulting curves that can be very rich, showing, for example, ranges with a negative differential resistance (Hatter et al., 2015; Huang et al., 2020), enhanced resolution in energy (Heinrich et al., 2018; Ruby et al., 2015; Kim et al., 2020), divergent behavior at the gap edge of the tip or situations in which $I(V)$ follows quite closely the superconducting N_s (Crespo et al., 2012).

In an STM experiment, one measures the tunneling conductance at an atomically well-defined position on the surface of the superconducting sample. To discuss the actual shape of the tunneling conductance measured with an STM at atomic scale, let us go back to Eq. (1). The term $|M|^2$ depends on the wave function overlap between tip and sample, which depends of course on the actual atomic level position of the tip. But in presence of an anisotropic band structure, the different wave function overlap also produces different contributions to $N_s(E - eV)$ from different portions of the band structure close to the Fermi level. The relative weight of these contributions varies at the atomic scale. Thus, both $|M|^2$ and $N_s(E - eV)$ are different at each atomically resolved position over the surface of the sample. This provides a certain spatial dependence of the combined term $|M|^2 N_s(E - eV)$. To find the values of the superconducting gap in different portions of the band structure from the tunneling conductance, one can write

$$N_s(E) = \sum_i \gamma_i \text{Re} \left(\frac{E}{\sqrt{E^2 - \Delta_i^2}} \right) \quad (3)$$

where γ_i is the relative weight of the contribution of a certain portion of the band structure and Δ_i is the corresponding value of the superconducting gap. For the schematic gap structures shown in Fig. 1C–F, one finds $N_s(E)$ as a sum of two BCS densities of states, each peaked at Δ_1 and Δ_2 .

But the actual gap distribution γ_i in a superconducting material can be smooth, with many Δ_i varying for different values and directions of the reciprocal space wave vector $\mathbf{k}$. Generally, this eliminates the divergent quasiparticle peaks of the BCS expression $N_{\text{BCS}}(E) = \frac{E}{\sqrt{E^2 - \Delta^2}}$ and produces instead $N_s(E)$ with rounded peaks at the values where the gap distribution Δ_i concentrates.

Note that rounded peaks are also obtained when taking into account lifetime broadening effects in the calculation of the density of states (Dynes et al., 1978). Lifetime broadening is a consequence of the pairing interaction and can considerably influence the BCS expression for the density of states. When lifetime broadening is large, it generally leads to an increased density of states at zero energy. Eq. (3) instead refers to a gap broadening due to the superconducting anisotropy and leads to a vanishing zero bias conductance as long as $\Delta_i \gg k_B T$ for all i .

Studying the γ_i and Δ_i as a function of the position on the surface, one can extract considerable information over the shape of the superconducting gap (Rodrigo and Vieira, 2004; Guillaumon et al., 2008). For example, in a two-gap superconductor with Δ_i distributed around two main values centered at $\Delta_{1,\text{avg}}$ and $\Delta_{2,\text{avg}}$, tunneling into a certain surface can produce a $N_s(E)$ with a contribution from portions of the band structure highlighting $\Delta_{1,\text{avg}}$ or $\Delta_{2,\text{avg}}$, depending on the actual atomic termination at each surface (Cho et al., 2017; Fente et al., 2018).

Even when scanning with the tip over a certain surface, one can find different contributions to the tunneling conductance at different atomic positions (Guillaumon et al., 2008). This does not mean that the superconducting density of states changes at atomic length scales (usually far below the superconducting coherence length). Instead, it shows that the contribution to the tunneling current at each atomic position depends on the contributions to the tunneling density of states from different places of the Brillouin zone. The overall superconducting density of states is by contrast the sum over the whole band structure and does not change as a function of the position in absence of disturbances of the superconducting condensate.

Behavior at defects and impurities

When measuring the surface of a single crystal, there are often impurities or defects. Charge screening implies an oscillatory density of states around impurities or defects, with a wave vector of the order of the Fermi wave vector k_F . The usual Friedel oscillations in a metal are a consequence of the spatial dependence of the charge density summed from the bottom of the band to the Fermi energy (Ziman, 1972). STM allows measuring the density of states on the surface at different energies E . Maps of the tunneling conductance $\sigma(eV)$ at a bias voltage $eV = E_0$ provide the spatial dependence of $N_s(x, y)$ at E_0 . These maps present often oscillations, at each energy E_0 , created by impurities or defects. The wave vector of the oscillations is related to the value of the electronic wave vector at the energy E_0 . Thus, the wave vector follows the electron dispersion relation as a function of the energy E_0 .

Note that these are not really Friedel oscillations in the usual sense. One can understand the oscillatory behavior observed by STM by using scattering of electrons confined to surfaces, as opposed to Friedel oscillations which are obtained by integrating the density of states over all energies. At the end, the result is similar, except that surface states scatter electrons and lead to an oscillatory signal, whereas the bulk band structure leads to Friedel oscillations whose projection on the surface is observed, too (Crommie et al., 1993; Heller et al., 1994; Crommie et al., 1995; Fiete and Heller, 2003; Petersen et al., 1998; Hoffman et al., 2002; McElroy et al., 2003; Hoffman, 2011; Pascual et al., 2004; Ortuzar et al., 2022).

The wave vector observed in the maps of the tunneling conductance $\sigma(eV)$ is two times the wave vector of the dispersion relation. Elastic scattering joins portions of the band structure at opposite wave vectors, $\mathbf{k}$ and $-\mathbf{k}$. One can write for the Fourier transform of the spatial dependence of the superconducting density of states with a modulation:

$$g(E, \mathbf{q}) \propto |V(E, \mathbf{q})| J(E, \mathbf{q}), \quad (4)$$

where g is the Fourier transform of the tunneling conductance, $V(E, \mathbf{q})$ is the scattering potential, J is the joint density of states, $J(E, \mathbf{q}) \propto N_s(E, \mathbf{k}_1) N_s(E, \mathbf{k}_2)$ and $\mathbf{q} = \mathbf{k}_2 - \mathbf{k}_1$ the scattering wave vector joining pairs of states at the same energy E (Hoffman et al., 2002; Fente et al., 2018). One can see that the scattering intensity and pattern depend on the scattering properties of the impurity or defect (the scattering potential $V(E, \mathbf{q})$) and on the density of states. For example, an impurity with a twofold anisotropy can

produce scattering along the impurity's anisotropy axis. Quasiparticle peaks located at the same gap values $E = \Delta_{i,j}$ also produce enhanced scattering. Thus, if one considers isotropic impurities or defects, one can obtain the variation of the superconducting gap in reciprocal space.

Key issues

In this section, a selection of superconductors with a density of states deviating from most simple s-wave BCS theory is presented. These systems have been widely studied during past years. One can probably safely state that there is an ample consensus about the interpretation of the observed tunneling density of states and its relation to the bulk superconducting properties.

Superconductors with a small gap anisotropy

In Fig. 3 the tunneling conductance in superconducting Al and Pb is shown (Martín-Vega et al., 2021). The density of states is zero within the superconducting gap and the quasiparticle peaks are well developed, following closely the BCS density of states $N_{BCS}(E)$. Similar results have been obtained for Nb, V, La or Re (Guillamon et al., 2008; Pan et al., 1998; Assig et al., 2013; Ruby et al., 2015; Fernández-Lomana et al., 2021; Senkpiel et al., 2020; Tonnoir et al., 2013; Senkpiel et al., 2022; Ast et al., 2016; Eltschka et al., 2015; le Sueur et al., 2008; Lo Conte et al., 2022; Kim et al., 2018; Nadj-Perge et al., 2014; Palacio-Morales et al., 2019). In spite of being elemental superconductors, some materials can have several bands crossing the Fermi level. When single crystalline samples are measured, the associated difference in the gap magnitude over the Fermi surface is well resolved. For example, Pb has two well defined values of the superconducting gap, as shown by Ruby et al. (2015). When nonsingle-crystalline samples are measured, there is often a small distribution of values of the superconducting gap Δ_i (see Eq. 3), following a Gaussian shape around the value expected from the single-gap BCS theory (Rodrigo and Vieira, 2004; Rodrigo et al., 2004a, b; Suderow et al., 2002).

A similar result is observed in many binary intermetallic superconducting compounds (Herrera et al., 2023b). Some are shown in Fig. 4. In these cases, often the distribution of Δ_i is more extended than in elemental superconductors.

Two-gap superconductivity in MgB₂

The best known example for a two-gap superconductor is MgB₂ (Nagamatsu et al., 2001; Rubio-Bollinger et al., 2001; Bud'ko et al., 2001). There are different bands crossing the Fermi level with small interband interactions and very different electron-phonon coupling. Bands derived from B σ -orbitals have a small overlap to bands from B π -orbitals. At the same time, there is a very strong electron-phonon coupling due to the in-plane B atom vibrations (Kortus et al., 2001; Choi et al., 2002). This leads to large values of the superconducting gap in the σ -derived bands, whereas the gap remains small in the π -derived bands. The tunneling conductance (Fig. 5) nicely shows the two superconducting gaps, and there is quite a wide distribution of gap values around the two main gap values ($\Delta_{1avg} = \Delta_{\pi} \approx 2.2$ meV and $\Delta_{2avg} = \Delta_{\sigma} \approx 7.1$ meV) (Martínez-Samper et al., 2003; Rubio-Bollinger et al., 2001; Giubileo et al., 2001).

Layered transition metal dichalcogenides

Transition metal dichalcogenides also have Fermi surfaces with different bands crossing the Fermi level (Inosov et al., 2008; Zhao et al., 2021). These compounds consist of blocks of a transition metal and two chalcogen atoms. They have a layered crystalline structure with weak bonding among layers. The arrangement of layers and of the blocks inside each layer is different for each polytype of the crystalline structure. The double hexagonal polytypes, marked as 2H, show superconductivity in 2H-NbSe₂, 2H-NbS₂, 2H-TaS₂, and 2H-TaSe₂. Their band structure consists mainly of two transition-metal-derived bands crossing the Fermi level, although there can be bands derived from the chalcogen (Johannes et al., 2006). In all cases except 2H-NbS₂, superconductivity coexists with a charge density wave (CDW). The latter leads to a large in-plane anisotropy, with opening of a gap in some portions of the normal-state band structure. The superconducting density of states, shown in Fig. 6, is compatible with a superconducting gap that is different in the two bands crossing the Fermi level in 2H-NbS₂ (Guillaumon et al., 2008). In 2H-NbSe₂, there is in addition a strong gap anisotropy (middle curve of Fig. 6), with a feature in the tunneling conductance pointing out a significant

Fig. 6 Tunneling conductance obtained in 2H-NbSe₂, 2H-NbS₂, and 2H-TaS₂. The tunneling conductance is normalized to its value at voltages well above the superconducting gap. Curves are displaced along the y-axis by 1.5 units of normalized conductance. The bias voltage is normalized to the BCS value of the superconducting gap Δ_{BCS} . reduction of the gap at some portions of the Fermi surface (Guillaumon et al., 2008; Noat et al., 2015). Furthermore, there is an intrinsic atomic-scale modulation of the superconducting properties through a pair density wave (Liu et al., 2021b). 2H-TaS₂ presents a significant correlation between the CDW and superconductivity, and an enhancement of the superconducting gap magnitude at some locations (Guillaumon et al., 2011).

2H-TaS₂ has the smallest T_c (below 0.15 K in the bulk) and presents the most peculiar superconducting properties, with a density of states that strongly varies as a function of the position (Galvis et al., 2013). Possibly, superconductivity is enhanced at the surface but influenced by normal underlying layers. There is a large zero-bias anomaly in single layers, which also appears in 2H-TaS₂ and has been associated with unconventional two-dimensional superconductivity (Galvis et al., 2014, 2013; Chen et al., 2019). Further experiments in single layers of dichalcogenides deposited or grown on different substrates show a reduction of the gap anisotropy and strong variations in the superconducting gap magnitude, which might decrease (as in 2H-NbSe₂) or increase (as in 2H-TaS₂) with the thickness (Navarro-Moratalla et al., 2016; Rubio-Verdú et al., 2020; Valencia-Ibáñez et al., 2022).

Nickel borocarbides

The rare-earth-nickel borocarbides RNi₂B₂C (with R = Gd-Lu, Y) present superconductivity up to about 16 K in nonmagnetic RNi₂B₂C (R = Lu, Y) and coexisting magnetic order for rare earths R with unfilled 4f shells RNi₂B₂C (R = Gd-Tm) (Cava et al., 1994; Bud'ko and Canfield, 2006; Canfield et al., 1998; Mazumdar et al., 1993; Müller and Narozhnyi, 2001; Cho et al., 1996, 1995).

Superconductivity in nonmagnetic RNi₂B₂C (R = Lu, Y) arises from a highly anisotropic electron-phonon interaction related to a nesting feature at the Fermi surface (Dugdale et al., 2008; Bullock et al., 1998; Dugdale et al., 1999). The superconducting gap is fully developed, although the quasiparticle peaks are very broad, pointing out a large distribution of values Δ_i (Fig. 7). There is a small feature for energies below the quasiparticle peaks, which could indicate a distribution of gaps around two values (Martínez-Samper et al., 2003; De Wilde et al., 1997; Sakata et al., 2000; Kaneko et al., 2012).

Measurements in magnetic rare-earth-nickel borocarbides RNi₂B₂C (R = Tm, Er) show a fully opened gap in the antiferromagnetic phase of TmNi₂B₂C and a closed gap in the ferromagnetic phase of ErNi₂B₂C (Fig. 7) (Crespo et al., 2006; Suderow et al., 2001). The latter points out that there is significant pair breaking related to the ferromagnetic phase.

Summary and future directions

Summary

From the examples discussed above, one can see that the tunneling conductance, as measured with STM, is a powerful tool to obtain the superconducting density of states and can lead to insightful descriptions of the superconductor. The tunneling conductance provides the energy dependence of the electronic properties and vividly shows the degree of anisotropy and of the difference of properties in multiple bands.

This text mostly discusses until now simple and well-understood examples where the distribution of values of the superconducting gap can be readily associated with the band structure or to the appearance of charge or magnetic order. This can be further explored by using the capability of the STM to scan spatially the superconducting density of states, which leads to direct measurements of the superconducting properties in real space, providing vivid images of the vortex lattice or of real-space anisotropic properties (Fischer et al., 2007; Suderow et al., 2014). In addition, the structure of the superconducting gap in reciprocal space can be also obtained.

Presently, STM is widely applied to practically any superconducting material as long as the surface can be prepared with sufficient cleanliness to allow for vacuum tunneling. There are many topical compounds and systems in which STM provides new information, which is mostly under debate. The following paragraphs aim to discuss the latter, presenting a brief view of recent advances in a few topical superconductors.

Future directions

The systems discussed below can be understood as “unconventional” superconductors (Mazin, 2023). The term “unconventional superconductivity” can be defined as “superconductivity with nontrivial Cooper pairing” (Mineev and Samokhin, 1999). A possible meaning of “nontrivial” is that the symmetry of the superconducting wave function is reduced with respect to the lattice symmetry. The broken gauge symmetry of the superconducting state, analogous to the broken time-reversal symmetry in a ferromagnet, would be the “trivial” situation. The breaking of additional symmetries combined with gauge symmetry might lead to “nontrivial” behavior, in analogy to the many kinds of wavy magnetic order (antiferromagnetism, ferrimagnetism, spiral magnetism, etc.). But the variety of behaviors that do not follow the basic principle of BCS theory of a spin-singlet Cooper pair wave function which is

isotropic in real and reciprocal space is very large. Thus, there are many authors who use the term “unconventional” for all those systems with an anisotropic or spatially varying Cooper pair wave function, often in materials where one can find enhanced electronic (Coulomb) interactions (Chubukov, 2023).

Cuprate superconductors

Cuprate superconductors have been intensively studied by STM (Fischer et al., 2007). The layered structure often leads to high quality surfaces where atomic features are visualized with beautiful detail and/or the superconducting density of states is measured accurately (Renner et al., 1998; Hoogenboom et al., 2001; Maggio-Aprile et al., 1997; Berthod et al., 2017). The superconducting gap anisotropy was measured by tracing the superconducting density of states as a function of the position in presence of scatterers (Hoffman et al., 2002; McElroy et al., 2003). Furthermore, studies of scattering on nonmagnetic pair breaking impurities vividly showed the sign changes of the superconducting wave function over different reciprocal space directions, demonstrating d-wave superconductivity (Pan et al., 2000).

Further work includes the observation of a pair density wave (Berg et al., 2009b, a; Agterberg et al., 2020). A uniform superconductor in which superconductivity coexists with a CDW presents oscillations of the density of states at the surface $N_s(\mathbf{r})$ at $\mathbf{q}_{CDW}$, $N_s(\mathbf{r}) \propto \cos(\mathbf{q}_{CDW} \cdot \mathbf{r})$ eventually on top of a background N_s (Guillamon et al., 2008). A pair density wave at $\mathbf{q}_{PDW}$ eventually shares the same wavevector as a CDW in the same system (the latter can be actually considered as a secondary order arising from the pair density wave, Agterberg and Garaud, 2015; Dai et al., 2018; Agterberg et al., 2020).

The oscillations of the combined pair density and Cooper pair wave function lead to a combined order parameter which changes sign as a function of the position (Berg et al., 2009a, b). The expected resulting oscillatory behavior of the combined order parameter is proportional to $\cos(\mathbf{q}_{PDW} \cdot \mathbf{r})$. It can be located at the same wavevector as the pair density wave although it changes sign (Liu et al., 2021b). Other sign changing modulated superconducting states, due to the interaction with magnetism, are known at ferromagnetic–superconductor interfaces and at high magnetic fields (Casalbuoni and Nardulli, 2004; Buzdin, 2005, 2012; Bergeret et al., 2001; Bergeret and Ilic, 2023). The $N_s(\mathbf{r})$ due to a pair density wave might eventually drop down to zero, if nothing else contributes to N_s except the combined pair density and superconducting order parameters. On the other hand, the expected oscillations of the pair density wave state in the density of states are due to the product of the pair density wave function with its complex conjugate, leading to $N_s(\mathbf{r}) \propto \cos(2\mathbf{q}_{PDW} \cdot \mathbf{r})$ and have different spatial dependencies when oscillations are enhanced at an impurity or at a vortex (Wang et al., 2018).

Nevertheless, the CDW oscillations of the density of states are never purely harmonic, for which one can also expect higher order density of states oscillations, purely from coexisting CDW and superconducting order. Thus, both features of pair densities waves, the measurement of the sign change in the oscillatory behavior and the behavior of higher order oscillations, are quite difficult to address and require careful comparisons of tunneling conductance maps made under different conditions.

The pair density wave has been studied using density of states as well as Josephson effect measurements (Liu et al., 2021b; Choubey et al., 2020; Edkins et al., 2019). It could well be related to observations of oscillatory behavior in other superconductors that have remained unexplained or unstudied (Agterberg et al., 2020).

Pnictide- and Fe-based superconductors

Pnictide- and Fe-based superconductors have been also intensively studied with STM (Hoffman, 2011; Paglione and Greene, 2010; Fernandes et al., 2014; Song et al., 2011). In one specific case, which is FeSe and related doped compounds, the atomic lattice has been observed by many groups, allowing for in-depth investigations of the tunneling conductance and of tunneling conductance maps. One of the defining features of these superconductors, and in particular of FeSe, is the structural transition between a high temperature tetragonal phase and a low temperature orthorhombic phase. While the lattice parameters in both phases are often very similar, the electronic structure turns out to be highly anisotropic in the orthorhombic phase. This leads to very anisotropic electronic features that have been termed “electronic nematic” in analogy to the nematic state of liquid crystals (Wang et al., 2022; Fernandes and Millis, 2013; Li et al., 2017; Chuang et al., 2010; Watson et al., 2015).

The nematicity is often associated with an antiferromagnetic order, except in FeSe where it has been linked to magnetic fluctuations and frustrated magnetism (Wang et al., 2015; Glasbrenner et al., 2015; Yu and Si, 2015). The nematicity leads to highly anisotropic scattering features in tunneling conductance maps, both in normal and superconducting phases (Chuang et al., 2010; Allan et al., 2013; Kasahara et al., 2014). Nematicity is intimately related to the orbital structure (Sprau et al., 2017; Rhodes et al., 2022; Kang et al., 2018; Yu et al., 2018; Hu et al., 2018; Liu et al., 2018; Baek et al., 2015; Li et al., 2020). The orbital contribution to the electronic band structure is considerably modified in the low temperature nematic phase. But the microscopic mechanism to enter the nematic phase is still under debate and requires more in-depth investigations of the local structure of superconductivity in FeSe.

Recent developments have allowed to address superconductivity in CaFe_4As_4 . This is a stoichiometric compound with a large critical temperature of $T_c = 35$ K (Iyo et al., 2016; Meier et al., 2016, 2017; Liu et al., 2020). Other pnictide- and Fe-based superconductors are nonstoichiometric at their highest T_c 's. CaFe_4As_4 presents two-gap superconductivity from tunneling conductance measurements (Cho et al., 2017). Studying tunneling conductance maps, one can extract the opening of the superconducting gap in different bands (Fente et al., 2018). Substitution of Ca or K leads to superconductivity coexisting with new

phases, such as hedgehog magnetism or ferromagnetism (Meier et al., 2018; Bao et al., 2018; Kim et al., 2021; Collomb et al., 2021). The superconducting gap and band structure in each phase are strongly modified (Llorens et al., 2021; Stolyarov et al., 2020).

Topological superconductors

Topological superconductors can be defined in analogy to topological insulators. In the latter, the usual orbital sequence of bands is inverted in the bulk. Often in light semiconductors, the s electrons form the conduction band while the valence band is formed by p and d electrons. When one takes a semiconducting compound having a heavy element, the shape of s orbitals is modified due to a stronger attraction potential and it might fall in energy sufficiently that the s -derived bands fall below the bands derived from p and d orbitals. Such an orbital sequence cannot be transferred into vacuum, where the influence of the heavy element is absent. Thus, bands must cross the Fermi level at the surface and lose band inversion in the vacuum. This leads to a surface state which is topologically protected and occurs forcibly in any semiconductor with band inversion.

In a superconductor with an orbitally antisymmetric superconducting order parameter (as opposed to the spin antisymmetric usual BCS state), there are also topologically protected surface states. The gap must close in some form at the surface, leading to a considerable modification of the superconducting density of states. This has been analyzed for the Landau framework of superconductivity by Sigrist and Ueda (1991) and Mineev and Samokhin (1999) and, more recently, within the topological classification by Schnyder et al. (2008) and Ryu (2023).

Many intermetallic compounds have band structure properties in the normal phase that lead to topologically nontrivial surface states. Some of them are superconducting. Efforts to observe unconventional superconducting properties have been made, for example, in the low temperature superconductor Au_2Pb (Martín-Vega et al., 2022). Indeed, a gapless state was observed. However, it is very difficult to separate a modification of the properties at the surface by changes in the band structure from modifications due to the presence of a topologically enforced surface state. The complexity arising from the surface is not yet resolved, being worsened in Au_2Pb because of the absence of an atomically flat surface. Further efforts have been carried out in $\beta\text{-Bi}_2\text{Pd}$, where the surface state is better defined, although the superconducting gap is fully open (Herrera et al., 2015; Choi et al., 2018; Li et al., 2019; Sakano et al., 2015; Lv et al., 2017; Kačmarčík et al., 2016). Important advances have been made in Te doped FeSe, where a Te p -electron-derived band is located near the Fermi level and can lead to band inversion and thus topological superconductivity (Zhang et al., 2018; Chen et al., 2018).

Possibly more promising are systems in which the appearance of unconventional superconducting properties is intimately related to strong electronic correlations (Kohn and Luttinger, 1965), such as heavy-fermion and ferromagnetic superconductor (Coleman, 2007; Aoki et al., 2011; Flouquet, 2005). Electronic correlations at the surface in these systems remain largely unstudied. Very recently, quantized states have been observed on the surface of a heavy fermion superconductor (Herrera et al., 2023a). This is a very promising result, which should help understanding surface features in unconventional superconductors.

One system, where topological superconductivity from electronic correlations is suspected since long, is Sr_2RuO_4 (Mackenzie and Maeno, 2003; Sigrist, 2005; Kallin, 2012). Here, atomically flat surfaces have been observed, leading to the determination of the normal-state band structure by defect scattering (Kreisel et al., 2021; Wang et al., 2017; Firmo et al., 2013). An opened superconducting gap has only been observed in absence of atomically flat surfaces (Suderow et al., 2009). This provides a clue about possible advancement routes. It is possibly important to take into account the influence of electronic correlations and surface states on the tunneling conductance at the surface.

Further work on the surface properties of potential topological superconductors might help to disentangle the expectations from theory in the surface state of topological systems, which include for instance Majorana modes presenting non-Abelian statistics.

Highly disordered superconductors

In the presence of disorder, electron screening is expected to decrease (Altshuler and Aronov, 1985). The influence of Coulomb correlations thus increases, leading to interesting behaviors in numerous thin film or layered superconducting systems where disorder is controlled with a tuning parameter.

The superconductor-to-insulator transition is a quantum phase transition whose properties have been studied in detail using tunneling conductance (Goldman, 2010; Goldman and Marković, 1998; Lin et al., 2015; Vinokur, 2023). At both sides of the transition, there is a gap, one is the insulating gap and another one is the superconducting gap (Sacépé et al., 2010; Roy et al., 2019; Valles et al., 1989; Butko et al., 2000; Sherman et al., 2012; Sacépé et al., 2011; Feigel'man et al., 2007). There is an intimate relation among both gap features (Vinokur et al., 2008; Bouadim et al., 2011; Bielejec et al., 2001). For example, the superconducting gap is considerably enhanced with respect to BCS theory when approaching the transition (Sacépé et al., 2010; Sacépé et al., 2008). Furthermore, the electronic properties both in the normal and superconducting phase are inhomogeneous (Mondal et al., 2011; Kamlapure et al., 2013; Ganguly et al., 2017).

The inhomogeneity is not ordered, and does not provide modulations of the density of states, which lead to the peaks in the Fourier transform observed in ordered metals. Instead, it produces long wave-length fluctuations without a particular direction (Bouadim et al., 2011; Postolova et al., 2020; Feigel'man et al., 2010; Carbillet et al., 2020). The actual electronic symmetry imposed by the crystal vanishes, which leads to slowly varying normal and superconducting state properties. Then, the fluctuations induced by Coulomb interactions are seen in the part of the Fourier transform of small wave vectors as a blob. Its dependence on the bias voltage is eventually connected to the energy dependence of the density of states, presenting enhanced fluctuations when the density of states increases, for instance, at the quasiparticle peaks (Postolova et al., 2020).

Conclusion

The full extent of STM, tunneling conductance, and its spatial dependence, provide important information about the nature of the superconducting state, helping to identify systems with fundamentally new properties. Here the very basic aspects, connected to BCS theory taught in the classroom, have been reviewed. The first part mostly deals with rather conclusive insights. The second part includes a few lines of work addressing topical problems in superconductivity, which, quite often, provide new questions, sometimes about the technique itself, that point toward the next step.

This hopefully serves as an introduction to the study of tunneling spectroscopy in superconductors, with the caveat that the reader should seek for further information, as some important developments have been certainly left out of the list, for the sake of clarity and space.

Acknowledgments

The author acknowledges help with figures and intense discussions with Edwin Herrera, Beilun Wu, José Gabriel Rodrigo, and Isabel Guillamón. Discussions, help, and guidance from Prof. Sebastián Vieira are also acknowledged. Support by the Spanish Research State Agency (PID2020-114071RB-I00, TED2021-130546B-I00 and CEX2018-000805-M), by the Comunidad de Madrid through program NanomagCOST-CM (no. S2018/NMT-4321) and EU program Cost CA21144 (Superqumap) is also acknowledged. The SEGAINVEX at UAM is acknowledged for the design and construction of STM electronics and of cryogenic equipment.
